RADIUM AS A SPECIFIC IN GIANT CELL SARCOMA.*

BY ROBERT ABBE, M.D.,

NEW YORK.

A SENSE of justice to a new subject has led me, from time to time, to present to this Society unusual cases of disease under the treatment of radium, so that fair judgment may be formed of the condition before, during, and after treatment. In that spirit also I would present for discussion some evidences of its intrinsic value in one group of cases representing a disease which permits of exact study, namely giant cell sarcoma, and demonstrates a specific action which has not been elsewhere spoken of.

CASE I.—In January, 1904, a lad of 17 years came to me with a soft tumor of his left lower jaw, of rapid growth, for it had been noticed only two months, and was thought by him to be an inflamed tooth. At that time, nearly six years since, I showed him at this society, with the desire that we should watch the change of the growth, as I hoped radium would affect it. The left lower jaw showed a soft tumor bulging the chin and lip forward, with the canine and two incisor teeth, which were loosely imbedded in it. Under the tongue the growth projected on the floor of the mouth, and rose half way up the teeth, where it had a fungating ulcerated area, purple and bleeding. The palpation by a finger within and without the growth was almost as soft as fluid. The bone had been wholly absorbed except a narrow strip on its lower margin which held the jaw ends together. There were two enlarged lymphatics beneath the angle of the jaw along the carotid. The growth was the size of a large English walnut.

Without previous experience with radium in this form of tumor, or with any recorded case in literature, I ventured an experiment with the inside growth by pressing a glass tube against it, with 150 milligrams strongest Curie radium (300,000). This I repeated for from twenty minutes to one hour for eight days. Then I saw a shrinkage of the mass, and of the fungous ulcer, which became pink and small. On the fortieth day the ulcer was healed and the inner side of the tumor hard and flat.

At four weeks the shrinking was progressing. Then I passed a knife into the tumor between the gum and lip. It entered as if the tumor were soft mush. It bled heavily, and I slipped the glass radium tube into the midst of it. On twelve occasions afterwards, this tube was left in the tumor for two or three hours each.

At six weeks the tumor still measured three centimeters thick, 2½ vertically and 5 cm. along the bone, but was shrinking. At each treatment the knife cut tougher tissue and gave less bleeding. At six weeks ossification had begun throughout the tumor, as felt by gritty points as the knife cut it.

At the tenth to twelfth week a sharp radium reaction set in, which caused me some alarm. The hot skin was fixed to the area of the tumor by cellulitis, which was only controlled by lead and opium lotion, but in a week this was gone.

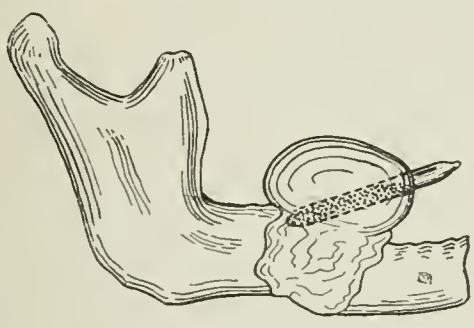
All treatment was stopped from that day. The teeth became solidly fixed in place. The soft growth rapidly ossified throughout. Then the ossific tumor shrank. The strangest thing of all is that each year has seen a continued reduction in the bone, so that now the jaw seems normal except that it is slightly thicker than on the opposite side.

It will be proper here to note this extraordinary retrograde of the tumor tissue, which is not at all like a destruction by caustics, but an effect of specific radiumization alone.

CASE II.—Sarcoma of the Jaw. In April, 1895, I was asked by Dr. E. G. Janeway to see a dear old lady of 86 years, who had a sarcoma of the jaw. I found a most intelligent patient, who had had a fracture of the left side of the body of the jaw a year prior, which had united. During the past six months she had noticed a tumor growing on the right side of her jaw. The bone was unbroken at the time we saw her.

A dense, firm, purplish ulcerated tumor grew up from the toothless gum at the site of the right lower first molar. The bone was largely involved, and the elastic mobility of the part suggested the almost, if not entire, absorption of the bone. The growth was highly vascular and bled on touch, as it had been doing continually when the patient sucked or ate food.

One week later she came to New York to be under my care, and I found the bone had now broken asunder and freely moved at the tumor.



I pierced the mass with a knife to make a channel to implant the radium tube. It bled very freely, and I endeavored to remove a small area for pathological study, but the pathologist reported that there was not sufficient for microscopic section. The radium tube contained 100 mgr. (300,000-

*Read at a meeting of the Practitioner's Society, December 3, 1909.

strength) Curie radium. It was stitched in place and remained accurately embedded for 6½ hours.

By the end of one week the growth had diminished one-half, and had grown pale and firm, with not the least tendency to bleed, even when pressed by a tongue depressor. Within a few weeks the growth had shrunk to the size of an ordinary callus, and firm union of the bone rapidly followed.

Four months later the tumor had gone. The patient lived out another year in fine health, and had not the slightest return of disease.

I have never had the least doubt of the tumor being giant cell sarcoma, nor had Dr. Janeway, who first saw it and considered it a hopeless condition of sarcoma, and said, "Abbe, perhaps you might try radium on that. Nothing else will do any good."

The extraordinary response to the one long treatment by radium was an unprecedented experience.

Case III.—Giant Cell Sarcoma of Both Superior Maxillæ. A boy of 7 years came under my care at St. Luke's Hospital in June, 1906, three and a half years ago, with an apparently inoperable tumor of both upper jaws.

The entire roof of the mouth, from one side to the opposite, and from the front teeth to the soft palate, bulged downward upon the tongue like a soft cushion. Both nasal cavities were obstructed to breathing by the upward growth of the same. In other words, the hard palate was entirely destroyed by the tumor, which had not only replaced it, but spread the upper gums so that the teeth did not match the lower jaw. The latter almost fitted inside the upper teeth.

It was evident that no operation short of removing both superior maxillæ would avail to cure the tumor. This was impossible.

With the two experiences just related in my mind, I gladly put radium to the test in this case of unparalleled size. I passed a knife into the roof of the mouth on one side of the midline, and inserted a cylindrical drill with which I punched out a cylinder of the soft tumor, more than an inch in depth. This instrument went straight up into the nasal fossa; the bone was entirely wanting. The same punch removed a like cylinder, an inch long, from the opposite side, and I could have removed one an inch and a half in depth. Microscopic study showed the growth to be active, and pure giant-cell sarcoma.

In these openings alternately, I buried a thin glass tube, containing 60 miligrams of purest radium bromide, leaving it 3¼ hours, 2 hours, 2 hours, 2 hours; total 9¼ hours during four days. The opening filled with lymph, and there was no fever. The mass became a little tender, and after one week was reduced in size. No other treatment was given.

Five months after treatment I saw him again, and my notes read, "central part all gone, margins flattened." At ten months my notes read, "curative change in every part; central part excavated to the normal depth of roof, sides still full, but ossified instead of spongy; nasal floor much lower."

Three years and a half have now passed with no further treatment, but with continued retrograde toward normal. The entire roof is ossified, and from the teeth toward the center the palate and mucoperiosteum are normal in contour and surface corrugations; while in the center is an undulating ossific surface, somewhat fuller than normal, but covered by new, smooth covering.

The nasal speech has cleared, and the nasal breathing is unobstructed.

To sum up this interesting case, we had a destructive soft sarcoma, filling the roof of the mouth and floor of both nostrils, in which all semblance of the bone from which it sprang was lost. Soon after severe radiumization there began a retrograde change in the mass, with ossification everywhere, and a reassembling of the original cells. The arch of the mouth and its covering have progressively approached normal; and the return to original appearance through shrinkage of the bone first built up in lieu of the sarcoma has not yet ceased.

Case IV.—Epulis, Giant Cell. Dr. R. observed a red, spongy growth on his upper gum between the incisor and canine. It bled at touch. His dentist cut it away and applied the galvanic cautery. In three weeks it reformed. Then it was excised, under cocaine, as far into the gum as possible. It was now more vascular and bled at the slightest touch. The microscopic diagnosis by Dr. Wood was epulis with giant cells. Examination showed a spongy, red growth, showing in front and behind on the gum between the teeth, about the size of a pea. Sucking or the use of a tooth brush caused bleeding.

In June, 1907, I applied 20 mgr. pure radium bromide to the growth, for ten minutes, twice.

In November, five months later, it was normal inside, and a little pink spot showed on the outside. Again I applied the same radium fifteen minutes, and some weeks afterwards another fifteen minutes, which rendered the gum normal. After two and a half years the part is still normal.

Case V.—Giant Cell Sarcoma of the Lower Jaw. In November, 1907, Dr. F. D. Weisse referred to me a woman with a malignant epulis.

Two years before that she had noticed a loose premolar, with a red growth in which it was bedded. Her dentist gave her a pencil to burn it with, but it grew larger. Soon after the tooth turned over sidewise and was pulled. Then the tumor grew faster and was cut out and cauterized. It was several times removed by knife and caustics. Dr. Weisse then removed it twice, as thoroughly as possible, but it recurred, and he put on a white powder to destroy it.

When I saw it, it was a red, spongy growth, as large as an olive, spreading out to both faces of the jaw, and filling the space between the teeth.

I applied radium, 60 miligrams, pure, in glass tube, burying it into the soft growth, after removing a piece for examination, which proved to be giant cell sarcoma. During eight weeks I made four applications, total 2½ hours. At the third month the growth was pale and small and inactive. At four months I cut out a bit for microscope. The report is, "Mostly connective tissue, in one corner a small amount of epulis tissue, with a few small, irregularly staining, giant cells. This area is surrounded by connective tissue, which is also penetrating into it."

It remains cured two years after.

Case VI.—Malignant Epulis. Mrs. B., aged 22, referred by Dr. Weisse. At the site of a lower bicuspid, which had been drawn, there grew for three months a red, spongy epulis, which filled the space between the teeth, and expanded the alveolar part of the bone. It was nearly as large as the one just spoken of.

Cutting out a section in the midst of it, I inserted 20 mgr. pure radium in a tube, three times, total, one hour. And, on one occasion a 60 mgr. tube for

thirty minutes. At three months the growth was flat and gone, except at the inner third, which was given more treatment.

I have lost sight of the patient, and cannot report later.

Case VII.—Giant Cell Sarcoma of the Right Upper Jaw. A gentleman of 65 years came to me January, 1908, with this history. For one year has bled from the nose every morning. A Paris surgeon had removed the lower turbinate bone and found a bleeding tumor behind it. He removed that and cauterized. Bleeding ceased for two weeks and recurred. A very able nose and throat specialist in New York recognized the trouble, and gave him violet rays for three weeks. At that time he came to me.

I found a solid, spongy, purple growth filling the right antrum, as shown by transillumination. The right half roof of the mouth bulged with a dusky, colored growth, soft to the touch, but covered by mucous membrane. The cheek was full below the zygoma, and at the side, and the softness on pressure showed that the bony wall of the antrum had been absorbed.

In June I resected the right upper jaw, which removed all the disease. In the fall, however, a little recurrence showed on the bony edge next the septum, and I again operated to clear all away.

In February, 1909, a little purple spot again showed at the septum bone edge of the opening in the roof of the mouth. To this I now applied strong radium on three occasions for a half hour.

Then the healed condition with no disease allowed a dental plate to be adjusted. At the end of a few weeks I was able to say there was not the least trace of disease, and he left for the country. Some months afterwards I saw him again, and the opening in the roof of his mouth, when the plate was out, permitted a thorough inspection. All was perfect. Some weeks later he met with an accident and lost his life. But this can be claimed as a cured case of grave malignant sarcoma.

Case VIII.—Mrs. S., aged 52, in February, 1905, consulted a nose specialist for bleeding from her right nostril, on using her handkerchief, and from her throat on rising each morning, for some weeks. He found a purplish, polypoid growth, quite friable and bleeding easily, lying on the interior face of the right middle turbinate bone. It was removed by wire snare. Dr. Jonathan Wright and Dr. Prudden both examined it. Dr. Prudden writes, "It consists chiefly of fusiform cells, packed closely together with a large number of very large and irregular shaped multinuclear cells (giant cells) among them. There are a few narrow strands of fibrous stroma and numerous thin-walled blood-vessels and irregular blood-channels. The diagnosis is giant-celled sarcoma."

Dr. Hutchinson makes the same diagnosis, and says it is the first he has seen in the nasal chambers, in his catalogue of fifteen sarcomas of that region.

In March, 1905, I operated to extirpate this disease thoroughly by cutting through lip and cheek, to approach the nasal fossa in front, removing the bone at the side of the nose after replacing the cheek. I found the disease not only extended on the side wall under the turbinate, but it had pushed out of the antrum. The antrum was packed full of the purplish sarcoma, but when the front wall was removed the lining of the antrum peeled out with the disease and left clean bone. The lateral nasal wall only was diseased bone, and this I removed. A prompt recovery followed, and for a year and a half she was perfectly well in this part. Examination by illuminating the nasal cavity was satisfactory, owing to the absence of the nasal wall.

A year and a half later a purplish, spongy growth at the root of the canine tooth where the bone was left, showed on removal renewed sarcoma of the same type. The tooth was loosening. A quarter hour radium application (20 mgr. pure) reduced the spongy mass and made the tooth tight.

A month later a return of the spongy growth extended along the alveola over the front teeth. Radium applied against this promptly flattened the growth. Several times it rose again and promptly subsided; the teeth became practically solid. At present there is a thin layer of growth along the gum, which is slowly going away without further radium, thus following the law of progressive disappearance for months and years after the radiumization.

Two other minor recurrences took place during the year at other points of the bony margin; but all are quiescent now under radium and will be instantly controlled if they again show trouble. It is nearly five years since the operation.

Case IX.—Meanwhile, on the same patient, appeared another typical giant cell sarcoma. Six months after the upper jaw operation a rapidly growing spongy tumor appeared on the outer side of the body of the lower jaw on the same side of her face.

This had no anatomical relation to the upper jaw. It involved the outer plate of the lower jaw, and the cancellous center for 1½ inches. Under ether I excised it, chiseled away all but a thin layer of the inner face of bone, and cleaned out the nerve and artery. It seemed probable this would not prevent a recurrence without radium, and I should have resected the best part of the lower jaw had I followed earlier surgical precedent.

Therefore a week after operation I laid a strong radium tube in the bony groove of the wound for three successive days, two hours each. The wound healed, and the bone is strong and without trace of disease, *four years after excision.*

Case X.—Giant Cell Sarcoma of the Pelvis. A young married lady developed a large, soft, bony tumor over the left sacroiliac synchondrosis, invading the sciatic part of the iliac bone. It was much larger than the fist when one of our most able surgeons attempted its removal. He curetted some of it away for examination, but was confronted by such profuse hemorrhage that he gave up its removal as impossible, and packed the wound. The growth enlarged, and the patient came under the care of another of our best hospital surgeons. *X*-rays were given until she became exhausted by toxemia of necrotic tissue in the wound. The diagnosis of spindle cell and giant cell sarcoma having been made, I was asked to try what radium would do as a last hope. There were two deep sinuses into the midst of the tumor, which was about the size of one's closed fist, and into these I placed strongest radium tubes, on three occasions, two hours each.

She improved during the next six months, gained seven pounds, and looked better. The growth has shrunken one-third or a half, and is firmer; the walls of the sinuses are now everywhere gritty with bone forming. If I may judge by experience, this improvement bids fair to continue, whether radium is used or not. Yet I think I will give it one more

treatment to insure more rapid progress, and because the fibrous predominated over the giant cell structure.

Case XI.—Giant Cell Sarcoma of the Sternum. A man of 59 years had a growing tumor of the breast bone for one year, though he had pain prior to that. It hurt him on jarring, so that he had to give up golf and move slowly. His physician gave him large doses of iodide of potassium, which produced no change.

In June, 1909, he was brought to me by Dr. Newton of Montclair. I found a large, expanding tumor four inches wide by six long, from the top of the sternum downward. It was soft, elastic, and crackled in a small part of its surface under finger pressure, though two-thirds of its surface was soft.

I made a slight cut in the skin at two places and applied a small steel cylinder with saw-teeth edge, with which I punched out a cylinder of the tumor. The instrument went through the fibrous capsule, replacing the bone, and sank toward the sternum three inches before reaching the inner wall. Thus the sternum had been expanded by the rapidly growing sarcoma from a normal half-inch to three inches thick, and all bone was wanting except some trifling surface pieces, like eggshell.

Into these punched-out holes and others made later, I sank several strong radium tubes and left them *in situ*, on three occasions, total 28 hours, in June. The pathological report was Giant Cell Sarcoma. At each withdrawal of the punch blood spouted out almost as if from an aneurysm.

I did not see the patient from June to October—four months. He had had a good summer. The tumors were reduced in size, and had a uniformly harder surface and no crackling. Again I punched this growth to introduce my radium and found it paler, firmer, and bleeding but little. The depth was now two inches where it had been three. The deep aspect of the tumor wall was also harder, as in front.

In October I gave it, by design, a very severe radiumization. At three points introduced a tube of 100 mgr. (300,000, Curie), and two of 20 mgr. pure German, each. These I left *in situ* 53 hours; (the longest exposure I had ever ventured) and advised no more treatment for six months.

Six weeks have passed, and we see to-night a flattening of the lower half, almost normal, and a slight dermatitis which has come from the outward radiations, to the under side of the skin.

If one may predict, we may expect to see a subsidence progress throughout the mass, with ossification and final shrinkage to normal in a few months without further treatment.

This review of a group of cases of one type of malignant cell growth, all showing peculiar, I may say unique, retrograde changes, tending always to return to the normal, gives a demonstration of the efficacy of radium, as clear to the clinical student as a demonstration of Euclid on a classroom blackboard.

There is no similar record in surgery, as far as I know. It may be supplemented by other remarkable cases in radium literature dealing with sarcomata and epitheliomata. The disappearance of a round cell sarcoma of the eyelid, which I have shown before this society (see Medical Record, October 12, 1907), is a notable one.

Again, in a remarkable destructive sarcoma of the humerus, where the bone had fractured in the growth, reported by Dr. W. G. Morton of this city (Medical Record, November 9, 1907), the skiagraphs show the cure by a radium treatment of six weeks. I have recently read a letter from the patient, who uses her arm as well as the sound one for all purposes, washing, ironing, etc., and remains cured after five years.

We have, then, to face a pathological and surgical problem which needs explanation. Why should an overgrown mass of a certain group of cells of the body, like these marrow cells, grow riotously and constitute a tumor which absorbs healthy structures opposing its expansion and destroy the body in a manner justifying its name "malignant?" And, again, when the powerful Becquerel rays emitted from radium penetrate the mass, why should the retrograde of all malignant cells proceed with orderly retreat, until the tumor has entirely gone? Or, again, how shall we explain the reassembling of original cells out of the mass, so as to shape the parts like the jaw bone, the roof of the mouth, the humerus, etc., so that the appearance and function are restored?

It is a bold speculation that permits one to venture in this field of biology when master minds admit ignorance of what constitutes the vital force which energizes each cell, and constitutes life as a whole. Yet we may be permitted to suggest that there are already known definite facts as to the nature of the rays, that they are electrons emitted with tremendous force, traveling in straight undeviating lines, each carrying an electric charge, if, indeed, they are not themselves electricity; speeding at 70,000 miles a second; retarded by dense objects, like masses of lead or steel, or bone or stone, only to escape beyond and resume their travels into space. It is recognized that radioactivity exists everywhere, but it is only when we concentrate it in our powerful little tubes that we can study definite effects.

The alpha, beta, and gamma rays have different electric charges, and different effects. The alpha are suppressed entirely in the glass tube.

The beta, carrying negative currents, escape feebly, and the gamma, carrying its own electricity, penetrate everything. Is it not conceivable that the riotous overgrowth of cells constituting a tumor may be due to a loss of equilibrium in the balance of electric forces sustaining the normal cell growth, and that the supply of one needed element—possibly positive electricity, possibly negative—will restore the balance, and enable the cells to resume their orderly growth.

This theory may encourage us to think further in that field, but it is purely "audacious and speculative," as Crookes says.

Huxley said "theories help us to bear our ignorance of facts," but conversely we may say *facts are the foundation of theories.*

The surgical estimate of giant cell sarcoma is one of a varied degree of malignancy. Wide removal of the apparent disease is undoubtedly more often curative than in other types of actively growing tumors.

The summary of operative results given in a paper read before this society four years ago by Dr. McCosh (*Annals of Surgery*, August, 1904) admirably showed the relative virulence and results to be expected. He rightly says that malignancy cannot be judged from the pathological report, as tumors of apparently similar structure vary. Of a number of operations on giant cell tumors, he cites cases of lower jaw in which he excised half the

lower jaw in two, and one-third in another. In the upper jaw he excised half the jaw once. He advises resection in long bones only when the growth is well encapsulated, but thinks amputation better in nearly all cases. In two cases of sarcoma of the thigh of this type he disarticulated at the hip. In two of the leg, he amputated in the mid-thigh. This reflects the general consensus of opinion on the operative attitude of surgery.

In the group of cases just narrated, it would have been necessary to resect one-third or one-half of the lower jaw in three, and half the upper jaw in two while the case of the boy with involvement of both upper jaws would have been hopeless.

The more grave case also of the extension and highly vascular sternal tumor would have given the patient a fatal hemorrhage if any attempt had been made to remove it, and it, at the best, could not have been extirpated entirely.

My conviction is that every case of myeloid sarcoma should be given treatment by radium before any operation and that we may expect many cures.

HORIZONTAL OSCILLATION OF THE EYEBALL IN CERTAIN RARE TYPES OF PONTINE LESIONS RESULTING IN SEVENTH NERVE PALSY.*

By L. PIERCE CLARK, M.D.,
AND
H. H. TYSON, M.D.
NEW YORK.

It is fairly well known that in Bell's palsy the so-called Bell's phenomenon, that of upward and inward or outward rotation of the eyeball, is a physiological act and not a pathological one, and is not pathognomonic of any special type of palsy, since it may be shown in the normal person. The character of the relationship between the lid closure and the upward rotation of the bulb is still in doubt. In many instances cocainization of the cornea may destroy the occurrence of Bell's phenomenon. But even then if a very intense effort of lid closure is made, so the lids are compressed or pinched together, the sign is once more made to appear. In other words, the Bell's sign would seem to occur under ordinary circumstances as a coordinated associated movement, but with spasmodic intentional lid closure the phenomenon involves the participation of other pontine elements. However this may be, nearly all observers agree that the usual type of globe movement seen in Bell's palsy is that of upward and inward or outward rotation. A few have observed the globe rotated downward in closure of the eyes.

About two years ago Schlesinger reported a case of horizontal globe vibration with closed lids which he announced as a hitherto undescribed variety of coordinate motion of the eyeball. It would seem that the report of his case is the only one published under a separate monographic title, although a few observers have noted isolated cases showing the phenomenon. Thus Dr. Starr has seen one case of this sort. In brief the phenomenon may be described as follows: In rare cases a more or less slow and deliberate lateral oscillation of the eyeballs occurs during a forceful attempt to close the eyes. The phenomenon occurs in some types of traumatic and rheumatic palsies of the facialis in which the nerve trunks or end branches supplying the orbicularis palpebrarum are greatly involved. In some cases at the beginning of lid closure the eyeball behaves as in Bell's phenomenon of facial palsy—the eyeball is moved upward and inward or outward; the voluntary impulse attempts transmission over the paralyzed facial nerve, but this being impossible, a part of the impulse overflows by way of the posterior longitudinal bundle and a coordinated associated movement, that of Bell's phenomenon, occurs. The new eye sign does not stop here. The more forceful attempt at lid closure being persisted in, the eyeball begins a see-saw oscillatory movement of forty to sixty vibrations a minute. The eyeball on the side opposite to the facial palsy participates in the same movement. The excursion of movement and the time of oscillation are maintained synchronously with the side of the affected facials. The new eye sign is partly under the control of the will at times. The movement may be inhibited completely or in part at the beginning or the end of attempted forcible lid closure. The oscillation is not controlled at all when the strongest effort of lid closure is made. The lateral oscillation occurs only on attempts to close the eyes; no other facial movement nor attempt at movement brings it out. In Schlesinger's case the ball phenomenon occurred in a medullary lesion of the seventh and twelfth nuclei, which gradually passed away as the primary lesion improved. The manner of disappearance of the sign in his case was interesting and significant. The ball vibrated at first on the slightest attempt of lid closure, a little later the sign was exhibited only under forcible closure. In a few days thereafter forcible lid closure caused a change in the plane of the globe vibration: it was no longer horizontal but absolutely without order, "wild." This in turn gradually abated into a typical Bell's phenomenon, followed finally by entire cessation of morbid movement as the facialis fully recovered from palsy.

The globe movements in our cases are still in the different phases of recovery, as just cited. Case I shows the state in its most typical phase. There is but little recovery of power in the orbicularis in this case as yet.

Apparently in this sign we have Bell's phenomenon plus something else. It is something more than a simple overflow impulse passing to the oculomotor nuclei. There is a disturbance also in the center for associated movements. Careful analysis of all cases shows a varying degree of paralysis of the conjugate movements. Thus in Case I the conjugate movement to the left exceeded same movement to right by 15 degrees, and the eyes move through an area of about 35 degrees, extending from a point about 30 degrees to the left of the median line to a point 5 degrees to the right of same line. The conjugate movement to the left in this case being stronger, we obtain the horizontal oscillation greater in that direction. Thus all the cases show a certain degree of defect of conjugate movement. Schlesinger failed to note this in his report and has apparently been at a loss to explain the sign in a completely satisfactory manner. Failure to note the disorder in the conjugate movements may lead one to think that various eye palsies exist. The defect is in the coordinate eye movements and not in the eye muscles *per se*. It is necessary, moreover, that the lesion in these cases shall be or shall have extended to the pons. The disordered mechanism occurs in the tegmental region of the

*Read at annual meeting of American Neurological Association, New York, June 20, 1909.

pons, at or just below the sixth nucleus. We also know nystagmus of a certain sort is often associated with paralytic lesion of this region in the pons.

The three cases upon which this paper is based are as follows:

Case I.—J. K., a boy of 16, contracted Bell's palsy of the right face, July 24, 1907. The lesion was complete and typical. At the end of ten months no spontaneous effort at regeneration having occurred under the usual treatment of this affection, facio-hypoglossal anastomosis was undertaken. The result in improvement in the movement of the muscles about the mouth and eye is due to this anastomosis.

The lateral oscillation of the eyeballs as seen at present has been practically unchanged as when first seen one week after the initial palsy. The sign is exhibited only in a forceful attempt to close the eyes. At the beginning of lid closure the ordinary Bell's phenomenon of inward and upward rotation of the eyeball is seen. Immediately after this movement the eyeball begins a slow, deliberate horizontal oscillation. The left eyeball also participates in the same movement. The movement is partly controlled by the patient, but not to any marked extent at the moment of most forceful lid closure. No other facial effort than lid closure induces the oscillations.

The eye examination shows: Vision in right eye varied from 20/40 to 20/20, due to spasm of accommodation. Left eye, 20/20. Sensibility of cornea, right diminished, left normal. The motility of each eye, which was tested separately, is apparently normal. Conjugate movements to the left exceed those to the right by 15°. There is orthophoria for distance, but very slight exophoria (0.5°) for near. The fusion power of muscles tested by prisms for distance shows: Adduction 12°, abduction 4°, circumduction 3°, decorcumduction 3°. The candle test shows no muscle palsies. Upon forced movements of the eyes to the extreme right or left a slight pseudanystagmus is produced; this is sometimes horizontal, at other times it is mixed.

The globe vibration on forceful closure of the lids moves through an area of about 35°, which extends from a point 5° from the right of the median line to a point about 30° to the left of the median line. The pupils are at times equal, at other times unequal, the right being the smaller, which is due to spasm of the sphincter pupillæ. The light and convergence reflex is normal. The orbicularis lid reaction is positive. Sensory reflex is positive, being more marked on the left side. The psychic reflex is positive. The color field test gave the red field largest, then green and white being the smallest. The color fields would seem to indicate a hysterical element as a complication.

Case II.—M. McC., age 43 years, in October, 1908, while driving truck, was thrown from his seat by force of a car running into his truck. He fell to the street, landing on right side of his face; was taken to Roosevelt Hospital, where diagnosis of compound fracture of right malar bone was made, and the torn orbicularis was sutured into place. Inability to close right eyelids (traumatic Bell's palsy). No diplopia, no paralysis of the individual muscles. Esophoria ½° distance. Orthophoria near. Vision: R. 20/40 with .75 20/35; L. 20/15. Excursion of conjugate eye movements to right 55°, and to left 40°, showing an excess of 15° to right over left. Upon forced attempts at closure of eyelids horizontal lateral oscillations appear, extending through an arc of 50° from 30° to right to 25° to left of median line, the deviation of greatest oscillation being toward the side with strongest conjugate movement. Sensibility of cornea diminished.

Case III.—J. M., age 12 years, on March 28, 1909, was kicked by horse on the right side of his face. Treated at Roosevelt Hospital for two weeks and three days. Diagnosis, lacerated wound of face and compound depressed fracture of right malar bone. Was sent to eye department on account of inequality of pupils. Right pupil larger than left; does not react to light nor convergence, due to paralysis sphincter pupillæ and accommodation. Cornea sensibility diminished. Has hemorrhages and changes about macula on right eye. Vision: R. 20/20; L. 20/20. No diplopia, orthophoria. Conjugate movement to right 40°, to left 50°.

On ordinary attempt to close eyes the right closes imperfectly, but by forced attempt may be closed fully. On attempts at forcible closure horizontal lateral oscillations occur, the eyes moving through an arc of about 30°, extending from 10° to right to 20° to left of median line. Thus, again, the greatest swing of the oscillation is toward the side with the stronger conjugate movement.

To produce this disturbance in the association-mechanism of the eye movements in the pons, there must necessarily be a lesion at the level of the sixth nucleus.

It would seem that the lesions in Cases II and III were hemorrhagic in the pons, as well as a direct traumatic neuritis in the peripheral branch involved.

Case I is not so easy to explain. In the one case of so-called Bell's palsy examined by Dejerine and Theohari the whole peripheral system was involved in an infectious neuritis. It is conceivable that this may have been the lesion in our own case. Then, too, the mooted point whether this case and a few others like it, occurring during the late poliomyelitis epidemic, might not have been in the nature of a poliomyelitis and not a true Bell's palsy *per se* needs to be thought of. However, one may view the matter, a lesion in the pons at the level of the sixth nucleus, probably hemorrhagic in character, must be postulated to fully account for this rare eye sign in some cases of seventh nerve palsy.

Finally one must admit that the manner in which a steady tonic contraction is broken into clonic contraction as seen in this eye sign is as obscure as that for ordinary nystagmus. The normal association of eye movements, however, enables us to understand something of the cause that produces it.

For the lateral movement of the eyes there are separate association tracts in the pons on the side toward which the movement takes place. Every normal movement necessitates an activity of these associate fibers, as well as a lessened activity of the antagonists, causing relaxation on the opposite side.

The intermittence in alternating innervation of the two sides causes the eyeball oscillations. If this be granted, the character of the movement may be neglected and the matter gravitates to the relatively simple problem of a disorder in conjugate movements of a paralytic nature. Their origin then constitutes a separate problem common to all forms, independent of special causation.

UNUSUAL MANIFESTATIONS IN CRETINISM.

By L. S. MANSON, M.D.,

NEW YORK.

In October, 1906, B. H. and O. H., male twins, were referred to me for a diagnosis by Dr. Alfred Michaelis of New York, with the following history: Born at College Point, L. I., January

Fig. 1.—B. H. at the age of 3 years.

9, 1883, were both wet-nursed until sixteen months of age; began to walk and talk at the proper age and appeared to be perfectly normal in every way except that they were extremely fat so that at the age of 4-5 years they weighed (O. H.) 101 pounds and (B. H.) 103 pounds respectively. Both had German measles and O. H. an attack of pneumonia at the age of 5. Otherwise the previous history is negative.

Present Illness.—In July, 1894, B. H., when 11 years of age, while playing out of doors suddenly became unable to walk and had to be carried home. He was kept in bed for two weeks by Dr. Arthur Kahn of New York City, now of Berlin, Germany, was dieted to reduce weight, and was given a course of cold baths. In January, 1895, while in London, England, he had a similar attack of sudden inability to walk when he was kept in bed for two days and also dieted by Dr. Walter Kilner of that city.

With the inability to walk there was considerable pain about the hips and thighs which troubled him occasionally, becoming, however, less and less frequent in occurrence. In 1896 he returned to New York, when it was noticed that his gait became peculiar. It is a waddling gait, the body swaying from side to side, and is manifest at the present time. In May, 1896, he was treated by Dr. Russell A. Hibbs at the New York Orthopedic Hospital where braces were used for a marked double flat foot and an extension apparatus was applied to stretch the shortened tendo-achilles for a period of four weeks after which it was noted that his walking improved slightly so that he could go up and down stairs better than formerly.

In the early part of 1906 he began to have spells of unconsciousness with tonic and clonic spasms and frothing at the mouth, which spells became more and more frequent until, in October, 1906, they had become of almost daily occurrence; were both nocturnal and diurnal, some severe and some mild and of very short duration, indicative of occasional attacks of petit mal besides the seizures of grand mal.

O. H., except for being very fat, showed nothing abnormal until 14 years of age when he developed a staggering gait. He walked like a drunken man and complained of severe pains about the hips. He, too, was treated by Dr. Hibbs at the New York Orthopedic Hospital by means of an extension apparatus, but without any improvement, the staggering gait remaining the same and a similar unsteadiness developing in the upper extremities so that he was utterly unable to use a typewriting machine and found considerable difficulty in using his hands to write. They were sent to public school at the age of 7-8 years, O. H. remaining until 17 and B. H. until 19, both being slow to acquire knowledge, B. H. being the more backward of the two. In both boys the hair of the scalp became thin and sparse while on the rest of the body the growth of hair was excessive, being compelled to commence shaving the face at the age of 13, B. H. six months

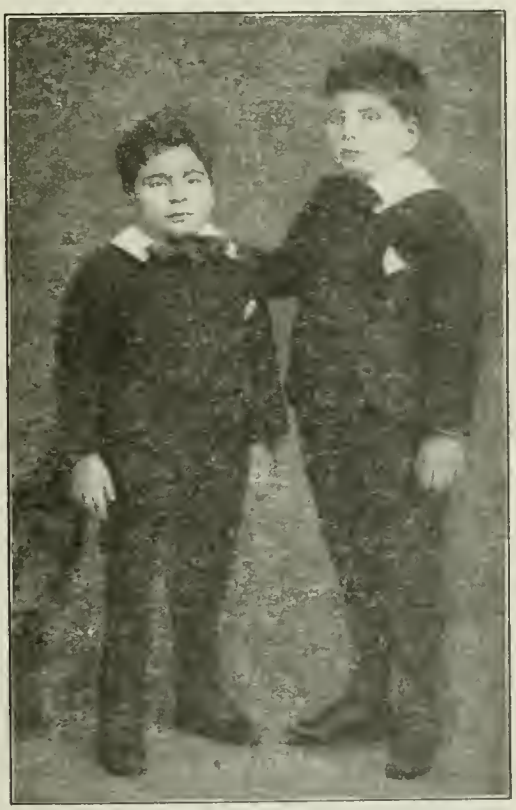


Fig. 2.—B. H. and O. H. at the age of 6 years.

sooner than O. H., in whom the loss of scalp hair took place later and the excessive growth over the rest of the body is not so pronounced.

Family History.—No history of goiter or cretinism is obtainable. The father died in 1894 at the age of 64 of cerebral hemorrhage (apoplexy). The

mother and three sisters are intellectual and healthy normal individuals. Physical examination reveals two well nourished boys with protuberant abdomen, very much under-sized for the age of 24 (1906),

Fig. 3.—Showing the results of treatment in the case of O. H.

O. H. being 58¾ inches and B. H. only 52½ inches in height. The greater portion of the scalp over the vortex of the skull is comparatively bald while the arms, legs, and trunk are excessively hairy, particularly so on B. H., as to resemble Jo-Jo, the Russian boy who for many years was a public exhibit.

Fig. 4.—Showing the results of treatment in the case of B. H.

The expression of their faces is dull and listless, made more decidedly so by the thick lips and broad alæ nasi; their skin is dry; and their gait is waddling, especially in O. H., in whom the loss of muscular coordination is so great as to make him distinctly ataxic in all four extremities. There is marked exaggeration of all the reflexes but no muscular changes. The genitals are overdeveloped;

Fig. 5.—Showing the results of treatment in the case of O. H.

motion at the hips is somewhat limited in all directions, and there is no perceptible shortening of the tendo-achilles. O. H. reports that he is jaundiced at times, is much constipated, has bloody stools from straining, occasional severe pains about the hips and thighs, and feels exhausted after slight exertion. Pulse 72, internal organs normal.

In B. H., who, aside from an occasional eczematous eruption on the front of the chest and infre-

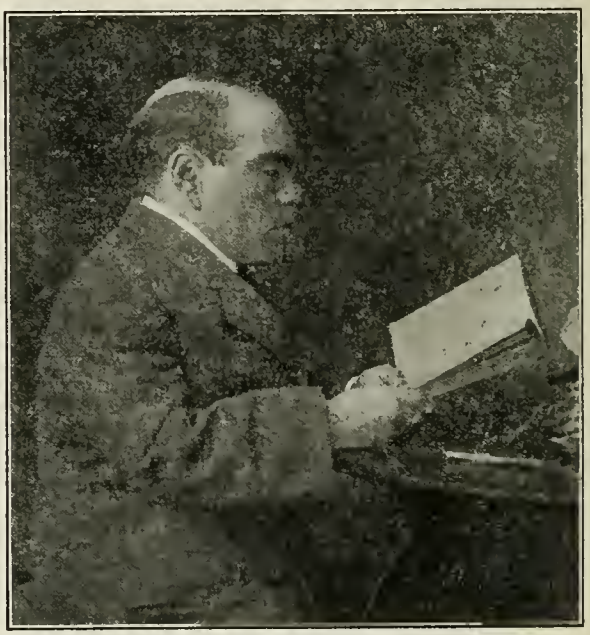

Fig. 6.—Showing the results of treatment in the case of B. H.

quent attacks of pain about the hips, feels remarkably well except during grand mal seizure, I found a myocardial insufficiency with marked bradycardia (pulse 52 to 64). There was a loud hemic systolic

murmur heard at the apex and transmitted to the vessels of the neck.

Mentally they represent boys of less than half their age at which time they apparently ceased to grow physically. They are extremely sensitive, however, refusing to come to my office on the same

Fig. 7.—O. H. at the age of 27 years.

day and never going out together lest they excite attention and public comment. When during the winter of 1907 Dr. Starr asked to show them at the centennial demonstration of the College of Physicians and Surgeons they reached the clinic by different routes and in different cars.

Upon careful palpation I found the thyroid gland in both boys to be so very rudimentary as to be scarcely perceptible and difficult to map out. I therefore diagnosed the cases as cretinism with unusual manifestations and thereupon began the administration of thyroid extract in gradually increasing doses.

In the case of O. H. I administered 15 grains of the extract daily, increasing the dosage by 5 grains every three days until he took 45 grains daily without producing any material change in bodily temperature and only slight acceleration of the pulse rate (72 to 90). Gradually the expression of his face and his mentality became brighter; the skin became moist; the hair of the scalp became thicker and more abundant; the heaviness and rotundity of body became perceptibly diminished (lost 12 pounds in weight); the ataxia in all four extremities became greatly improved so that while he still walks with a waddling movement and his reflexes remain markedly exaggerated he is able to write without difficulty, has acquired the use of the typewriting machine with sufficient skill and dexterity to enable him to earn his livlihood, and has grown up to the present writing fully 1⅜ inches in height. Photos showing the more beneficial results of the treatment in the case of O. H.

In the case of B. H the administration of the remedy was not productive of such happy results, for with the increase to 25-30 grains of the extract his pulse rate would run up to 150 and over and he would display such excessive irritability that the drug had to be discontinued. In spite of its periodical and incomplete administration, however, the epileptic seizures were greatly modified.

Fig. 8.—B. H. at the age of 27 years.

For eight months after treatment was commenced he had no seizure, then he had two in rapid succession and of mild character, though of grand mal type, then another mild seizure, December 5, 1907, in the consultation room of Dr. Louis Fischer, who kindly volunteered to treat the twins during my absence abroad and who reported that "the duration of the seizure was about thirty seconds and looked like petit mal instead of grand mal. The patient suddenly losing consciousness, appeared to hear my talking to him but could not answer; breathing very rapidly and shallow which, gradually subsiding, he resumed the conversation where it was left off as though nothing had happened." At one time after withdrawing the thyroid extract Dr. Fischer was obliged to administer 5 minim doses of adrenalin solution to reduce the rapid pulse rate. In addition to the marked improvement of the epilepsy, the

seizures during the past two years being few and far between, the hair of his scalp became thicker and more abundant, the expression of his face became brighter and more cheerful, and he became decidedly more intellectual, but without any noticeable increase in height.*

The closest possible investigation furnishes no history of an infectious fever, erysipelas of the neck, or rheumatism (unless the pains in the lower extremities with shortness of the tendo-achilles and limitation of motion at the hip joints be rheumatic in nature) as a possible forerunner of thyroiditis.

Why defective thyroidation should produce, besides intellectual and physical enfeeblement and retardation, epileptic seizures in the one and muscular incoordination (ataxia) in the other of these twins, the reader can conjecture as well as I, for as yet all is theory and conjecture. It does, however, lend some color to the doctrine of Schiff that the normal thyroid elaborates some substance as yet not isolated nor its characteristics determined, which is indispensable to the proper performance of the functions of the nervous system.

616 Madison Avenue.

THE DIAGNOSIS AND TREATMENT OF PEPTIC ULCER.†

By CHARLES E. NAMMACK, M.D., LL.D.,

NEW YORK.

PROFESSOR OF CLINICAL MEDICINE, CORNELL UNIVERSITY MEDICAL COLLEGE; VISITING PHYSICIAN TO BELLEVUE HOSPITAL AND TO ST. VINCENT'S HOSPITAL.

During the last twenty years a vast literature has accumulated regarding the subject of stomach disorders. Specialists in gastroenterology have elaborated the importance of this or that clinical symptom of stomach indigestion, with a refinement of nomenclature and with an emphasis of utterance more remarkable for its fervor than for its importance to the sick man. A part has been magnified at the expense of the whole, and, in our desire as general practitioners to understand the intricacies of specialism, we have been led into the error of treating a sick stomach instead of trying to cure a sick man. Faddists in diet have been hailed as prophets, and ingenious mechanical and electrical local devices have been sought for, to improve men going down under the stress and strain of modern life, instead of securing for these men restful sleep, fresh air, sunlight, physical exercise, proper activity of the bowels, kidneys, and skin, and that mental content which comes with a realization of the fact that the chief end of life is not the accumulation of riches and honors.

The individual equation in disease has given place to the "feudality of classification and the tyranny of established rule."[1] We have been led away from the fact that while each factor of the digestive process has its own function to perform, all are interrelated, not only with all other factors of the alimentary apparatus, but also with all the other mechanisms of our organism, and especially with our nervous functions and with our mental processes. But while this absolute interrelational integrity must, as a rule, be maintained for the purpose of perfect health, nutrition may be kept up in exceptional cases, even after the removal of the entire stomach by surgical intervention, or in the almost complete absence of hydrochloric acid from the stomach, seen in certain cases of progressive pernicious anemia. Nature here, as elsewhere, seems capable of applying the principles of adaptability and vicarious action. We must also bear in mind that the accurate, complete, and painstaking researches of that pioneer American physiologist, Beaumont, demonstrated, as long ago as 1823, that the recuperative and regenerative power of the stomach was sufficient to atone not only for violent inflammation, but for extensive trauma.

Before we can apply these principles to the consideration of the subject of peptic ulcer, it is necessary to define exactly what is meant by that term. The gastric mucosa, like other surfaces o fthe body, may suffer ulceration from chemical, mechanical, or toxic irritants, the acute infections, tuberculosis, syphilis, scurvy, diabetes, and puerperal septicemia, but it is scarcely proper to regard these as cases of peptic ulcer, even though they may be produced by the eroding action of the gastric juice upon devitalized tissue. True peptic ulcer is none of these, but is "a more or less progressive destruction beginnig in the mucosa and sometimes extending to and even through the deeper layers of the stomach wall, of the nature of a degeneration or a necrosis."[2] Sometimes we recognize this condition easily at the bedside, but at other times it is found only in the deadhouse in cases unrecognized during life. In one thousand consecutive autopsies at Bellevue Hospital, Harlow Brooks found it existing in nine bodies, in only two of which had it been discovered before death.[3] Cases fall into two groups: 1. Acute peptic ulcer in chlorotic young women; 2. Chronic or indurated peptic ulcer in men past middle life. Apparently then there is some common factor which lowers vitality of tissue and is operative in early adult life of women and after middle life in men. This factor is at present unknown, but there is much analogy to suggest that it may be a trophoneurosis akin in its manifestations to the visceral lesions, apparently secondary to neurotrophic disturbance, which sometimes occur in angioneurotic edema.[1] This trophoneurosis may be the factor which, added to destruction of gastric epithelium with disturbance of the circulation in the stomach and hyperacidity of the gastric juice, produces the combination permitting autodigestion. Erosion alone does not cause peptic ulcer, blood stasis in the gastric circulation exists only in a few isolated cases and is not found in the thousands of cardiac cases where we would naturally expect it to occur, and hyperchlorhydria exists in thousands of other cases without producing peptic ulcer when the nervous system is not below par by reason of overwork, underfeeding, business troubles, or domestic infelicities.[4] Again, hyperacidity is by no means constant in gastric ulcer, although when it does exist it may prevent healing of the ulcer and may cause it to become chronic.

Absence of this neurotrophic disturbance then may be the answer to that question which has always puzzled us, "Why does not the normal healthy stomach digest itself?" Another answer is, however, clamoring for recognition in the literature. This is based on the idea that certain endogenic and exogenic poisons, which select the gastric mucous membrane for their special region of attack, contribute to the formation of typical round ulcer of

*Unfortunately I did not have them photographed at the time treatment was commenced, not realizing that the case would develop so many interesting features to make it sufficiently worthy of record.

†Read before the Alumni Society of St. Vincent's Hospital, October 27, 1909.

the stomach.[3] And Weinland has described an antipepsin ferment which was supposed to reside in and to form part of the gland cells, thus intimately protecting the same from autodigestion by these poisons, and has stated that local deficiency of these antibodies was the predominant factor. But how are we to explain this local deficiency? Turck has produced genuine induced round ulcers in every experiment in which he fed bouillon cultures of the colon bacillus to dogs and believes that the etiology is dual: 1. There is some toxic status which overcomes the natural resistance, resulting in cytolysis; 2. Some chemical substances are formed in the alimentary tract, which, when absorbed, neutralize the protective bodies in the blood and tissues, resulting in autocytolysis.

The cardinal symptoms of gastric ulcer are pain after eating, epigastric tenderness, vomiting usually of very acid material, hematemesis, and blood in the stools. Blood in the vomitus and feces may not be obvious, and microscopic, spectroscopic, microchemical and chemical tests for its determination may be required. Secondary symptoms are anemia, emaciation, weakness, nervousness, melancholia, headache, thirst, and constipation. Complications due to hemorrhage, perforation, fistula, subphrenic abscess, perigastritis with adhesions, distortions of the stomach due to indurative and contractive changes around the ulcer, and carcinoma developing on the site of a chronic ulcer, will each add its own modification of the typical picture.

The objective signs elicited by physical examination add but little information to the patient's story. Localized tenderness is the most valuable sign. Palpable tumor may sometimes be felt in chronic ulcer, either from the thickened ulcer itself, from muscular hypertrophy or adhesions, or from exudate. The results from gastric analysis are very variable, according to the type of the ulcer. The finding of blood in the gastric contents or in the stools is of more importance than any other sign.

When this typical combination of symptoms and signs exists, there is very little doubt as to diagnosis, but in many cases both symptoms and signs are very indefinite and diagnosis is obscure. In the differential diagnosis we must exclude gastralgia, hyperesthesia, hyperchlorhydria, hysteria, gastritis, pregnancy with hyperemesis, uremia, cancer, gallstones and renal stones, aneurysm of the abdominal aorta, gastric crisis in spinal diseases, and hemorrhagic erosions with exfoliation. In gastralgia the pain bears no relation to taking of food, pressure relieves the pain, blood is absent. Yet more than one case treated as gastralgia for a long time has confounded the medical attendant by eventuating in a copious hematemesis. Simple hyperchlorhydria rarely has vomiting or hematemesis, very little tenderness, pain appears long after food or at night, proper albuminous diet with alkalies usually promptly relieves. Simple hyperesthesia shows pain at once after meals, irrespective of kind of food or of its temperature. Hysteria has no severe pain as a rule, but prompt vomiting after eating, and shows the stigmata of hysteria elsewhere. Gastritis has obvious dietetic indiscretion, usually fever, anorexia, toxemia, and tenderness and pain which are diffused. Uremia shows characteristic urinary findings. Cancer will often have debility and emaciation preceding the other signs; the pain is more constant and more independent of food; vomiting gives less relief than in ulcer, the vomitus shows little or no hydrochloric acid, and may show lactic acid after a Boas test meal together with ill-digested food and the Boas-Oppler bacilli; if hematemesis occurs, it will be of coffee-ground type. In chronic ulcer causing a pyloric tumor with dilatation of the stomach the differentiation may be impossible—before operation. When cancer is engrafted upon an old ulcer, there is increase in pain, gradual lessening of hydrochloric acid, and tumor increasing in size and assuming a more nodular character. The crucial test for hemorrhagic erosions with exfoliation is the finding in the lavage water of bits of mucous membrane, but these have been found in many stomach conditions without hemorrhage.

Gallstones may present every symptom of gastric or duodenal ulcer, and experienced surgeons have often been deceived. The importance of testing of urine for biliverdin by Rosin's test in every suspected case has lately been brought forward.[7] Spinal disease usually has symptoms and signs which can be elicited by physicians who take the trouble to make routine neurological examinations of their cases.

Duodenal ulcer was formerly described independently of gastric ulcer and was thought to exist in about 6.6 per cent. of all peptic ulcers only, but the surgery of recent years has shown that the proportion is ever increasing and is perhaps 1 to 1. In the last reported 200 cases of the Mayos, 98 were duodenal, 87 were gastric, and 15 were independent of each viscus.[2] Duodenal ulcer depends upon the same main etiological factors as gastric ulcer, and its symptomatology is almost identical. Cases present under four types: (1) Those indistinguishable from gastric ulcer in symptoms and signs; (2) those with hemorrhages from the stomach or bowel, or both, and with no other symptoms; (3) those with symptoms resembling biliary colic, especially the pain, tenderness, and intermittent jaundice; (4) the perforative cases which simulate also gall-bladder perforations and appendicitis. Einhorn believes that he can make the diagnosis clinically with some certainty by the thread test showing a distinct blood spot at a distance of 58 to 60 cm. from the teeth.[8]

In the treatment of gastric ulcer prophylaxis is difficult because the etiology is obscure. Curative treatment must first take cognizance of the variety of ulcer present, whether acute or chronic. Study in the post-mortem room shows that four out of five cases of simple acute gastric ulcer heal during life.[9] But to bring about this happy result early diagnosis is necessary in order to prevent complications, and the strictest discipline is essential, no neglect in hygiene, diet or medcine being permissible. Of prime importance is rest in bed for a period of four to six weeks with very gradual transition to active exercise, a period of rest after each meal being enforced for months after the patient is up and about. Attempts at feeding must also be tentative, as there is no general rule applicable to all cases. Starvation may be necessary for the first few days, and is usually well borne if saline enemata be administered to supply tissue loss and maintain the moderate needs of patients who are absolutely at rest. Nutrient enemata of six ounces given every six hours may next be tried, and, later on, mouth feeding commenced with small quantities of milk and lime water to which the addition of milk of magnesia may be necessary. After several days, broths and raw eggs

may be added, and after four weeks finely divided albuminous foods, such as minced meats, white fish, chicken, tender beef and light potatoes. All coarse, irritating and spicy rich foods should be avoided for several weeks. The best drug is undoubtedly bismuth, the constipation of which can be overcome by combining with it light carbonate of magnesia. Silver nitrate is also highly recommended. Severe pain may require morphine or orthoform, which last drug was formerly thought to be an aid in differentiating the pain of gastralgia from that of gastric ulcer.[10] Other symptoms must be met as they arise.

Although no single rule applies to all cases, certain clinicians have laid down details of methods, with which their names are identified and for which they claim the best results. Thus W. V. Leube[11] reports 547 non-hemorrhagic cases with 90 per cent. cures—the majority in from four to five weeks, and no deaths; and 90 per cent. cures with 2.5 per cent. deaths in hemorrhagic cases. His treatment is based upon four cardinal points: (1) Rest in bed; (2) Karlsbad water, a quarter liter, taken lukewarm; (3) hot poultice to epigastrium, except during hemorrhage, when ice bags are used instead; (4) light diet of high nutritive value and easy digestibility.

Lenhartz's method is based on the theory that ulcer is prevented from healing because of mechanical stretching of the organ, hyperacidity, and anemia. He opposes the main ideas of the usual "abstinence cure" and advocates: (1) Concentrated albuminous food continuously; (2) rapid increase of nourishment; (3) absolute rest for four weeks with ice bag for the first ten days. Senator adopts a middle course and advises glutin or gelatin for its soothing and hemostatic effect, fats for their counteracting effect on the hyperacidity and to soothe the ulcerated surface, and sugar because it is easily digested and nutritious. Later he adds eggs, chopped meat, and jellies.

The above medical measures will be successful in the vast majority of cases of acute peptic ulcer, but many cases certainly fail under medical treatment. The proportion of these failures is variously estimated by different observers, the average mortality in 20 large series of cases collected and quoted by Musser being 8 per cent.[14] Surgeons, however, claim that recurrence takes place in nearly half the cases after "medical cures,"[12] and that surgical interference, on the other hand, shows an ever diminishing mortality in each succeeding year. While agreeing with the medical men that rest for the stomach is the principal factor in cure, the surgeons claim that this rest can only be secured by the surgical operation of gastroenterostomy, preferably by the posterior loopless jejunal method, thus providing sufficient gastric drainage.

It is difficult to draw absolute indications for surgical interference, but any case of gastric ulcer which has resisted *rigid* adherence to the principles of rest, diet, and medication for two months, should be submitted to the surgeon because such a case has become chronic and liable to the occurrence of complications, such as perforation, hemorrhage, perigastritis with adhesions or abscess, stenosis of an orifice, and constrictions causing deformities. A case with early slight hemorrhage does not require surgical intervention, and even a single large hemorrhage does not demand operation until medical measures have failed to control it. This applies only to acute cases. A gastric ulcer which, after causing dyspeptic symptoms over a prolonged period, eventuates in hematemesis should be operated on, as the ulcer is probably an old one, the tissues are indurated, spontaneous healing is difficult, and thrombus occurs less readily. Persistent recurring hemorrhages, with short intervals between, demand operation. Perforation demands immediate operation, as every hour's delay costs the patient 8 per cent. of his chances of recovery.[13] After closing the perforation, a gastroenterostomy should be performed in all cases.

Hour glass contraction and other constrictions of the stomach demand the establishment of proper drainage by suitable surgical procedure.

Conclusions.—1. The crux of the diagnostic situation in stomach disorders is not the study of the stomach itself, but is the study of the individual, including his nervous system, cardiovascular system, renal and other excretions, and his entire makeup.

2. Cases of acute uncomplicated peptic ulcer need not be immediately handed over to the operating surgeon.

3. Cases of chronic, recurrent, or complicated gastric and duodenal ulcer are surgical cases.

MODERN VIEWS CONCERNING DISEASED TONSILS.*

BY C. M. HARRIS, M.D.,

JOHNSTOWN, PA.

OPHTHALMOLOGIST AND OTOLOGIST TO THE CONEMAUGH VALLEY MEMORIAL HOSPITAL, JOHNSTOWN, PA.

DURING recent years striking advances have been made in nose and throat surgery. The diseased tonsil has received due attention from progressive operators, and to-day there can be little excuse for the incomplete operation and the unsatisfactory results which have so characterized tonsil surgery in the past. Specialists have discussed the matter to a standstill and many articles have appeared in the journals. In spite of all this I believe that we as a profession have not given the attention it deserves, and I am quite sure that a careful consideration of the anatomy and pathology of these organs would change the minds of many who are now quite conservative or indifferent.

Conditions other than acute inflammation or ex-

*Read before the Northern Cambria Physicians' Association at Patton, Pa., August 4, 1909.

treme enlargement are frequently ignored; but this should not be, as when a tonsil once becomes diseased it is apt to continue its malign influence, causing an extension of inflammation which affects the ears and nasal passages or gives rise to various ills in remote parts of the body.

The subject is a large one and no attempt will be made in this paper to touch upon other than the more important points.

The faucial tonsil is a structure of varying weight, shape, and size, and is permeated by eight to twenty crypts, which usually penetrate to its base. Its substance consists of lymphoid tissue, which surrounds the crypts and is divided and supported by a fine connective tissue stroma. Its inner or mesial surface is covered with mucous membrane, which also lines the crypts. The outer surface is invested with a layer of fibrous tissue, and it is by these that the organ is totally encapsulated. It rests upon, and is loosely attached to the fascia of the superior constrictor muscle of the pharynx through which pass its principal blood-vessels. Anteroposteriorly, it is bound by the pillars of the fauces which unite above, forming an arch sometimes partly concealing the upper portion of the tonsil, by a membranous fold called the plica supratonsillaris. A membranous investment of the anteroinferior portion of the organ is commonly seen. This is called the plica triangularis and is an embryonic remnant. Inferiorly the pillars diverge and enter into the tissues at the base of the tongue and the lateral wall of the pharynx.

That the tonsil is not a vestigeal organ is proven by the fact that it is more complex in man than in lower animals. Clinically, it need only concern us when in a pathological condition, and broadly speaking it may be considered pathological when it is subject to acute or chronic inflammation or is sufficiently hypertrophied to cause obstruction to nasal breathing, affect the speech, hearing, or other normal processes.

The condition of acute tonsillitis is well known to all of us, but I feel positive that its importance is often underestimated. In addition to the usual symptoms it has given rise to otitis media, edema of the glottis, acute endocarditis, rheumatic fever, pneumonia, and gangrene of the lung. I have personally treated one case where septicemia and hemorrhagic nephritis resulted. Acute attacks may be followed by complete recovery, or what is more likely by a low grade inflammation causing hyperplasia of the glandular element presenting a soft regular enlargement of the organ, or of the connective tissue element, giving an irregular appearance and toughened fibrous character. If true hyperplasia is not present, the enlargement may be due to passive congestion and its consequences. In any of these chronic conditions the cryptic membrane is very apt to be adversely affected, lowering its resisting power to invading bacteria, and exacerbations are thus invited. Under such conditions infectious material is often found in the crypts, which exudes and causes fetid breath. At other times it is a potent factor in deranging digestion. Streptococci and staphylococci are normally found in these crypts and tubercle bacilli not infrequently so. Through lack of resistance, general infection is invited, and primary tuberculosis of the tonsil has undoubtedly been seen. Enlarged and diseased cervical and submaxillary glands frequently attain such a condition by acting as barriers to the influence of offending tonsils.

Many of us have been prone to look only upon the large tonsil with suspicion, and it is true that this may be more obstructive, but the smaller diseased organ is often more important. The small ones which we see during adolescence or adult life are often considered to be atrophied. They really have degenerated and are in some instances a distinct menace to health. Many of them are more obstructive than they look and thorough dissection will show they are bound in and forced upward, impeding nasal breathing and affecting the hearing by pressure and congestion about the Eustachian orifices. This type does not project to any extent beyond the pillars and the use of the tonsillotome under these conditions is worse than useless. I have had patients where throat symptoms and rheumatoid pains were coexistent and suitable treatment of the diseased tonsils was followed by a disappearance of the pains. In some cases it is useless to treat middle ear discharges without first clearing out offending tonsils and adenoids.

The pharyngeal tonsil histologically presents a structure simulating that of its faucial neighbor. It possesses crypts and may be the seat of acute inflammation which is often undetected. In its hypertrophied form we know it as "adenoids" or "adenoid growths." As such it impedes nasal breathing and associated or alone causes impaired speech, chronic rhinitis, cough, mouth breathing, middle ear disorders, permanent facial deformity, and a profound evil influence on the mentality and general health. Mouth breathing is an evil of grave consequences. The face becomes narrow, a vacant expression is present, the teeth are poorly arranged, the palate is highly arched, intruding upon the nares, and the dust-laden unwarmed air is drawn directly against the lower pharynx and into the lungs. The outcome of this is a narrow-chested, weak-lunged individual whose entire respiratory tract is weakened, making him quite susceptible to any disease affecting these parts, and no small number of tuberculous cases can point to a similar history and condition.

On account of the aforesaid reasons the offending structures should be dealt with during early childhood. An opportunity to properly develop is thus given the parts and habits of good breathing may be acquired. It is remarkable how quickly the improvement in breathing is noticed. I have treated cases where sleeping had been a very uncertain matter on account of obstruction. In two hours after the operation quiet free breathing resulted. An able dentist may do good service by correcting the all too common palatal deformity, but as this takes time and is necessarily expensive comparatively few avail themselves of this service. Whether or not tonsils have a function has been discussed at great length by numerous investigators. No convincing explanation has been forthcoming, and while a normal tonsil may be a good thing to have, possessing an abnormal one is quite a different matter. The true function may at some time be discovered, but it may be said that evil consequences have not been noticed after the total removal of a pathological tonsil.

For many years it has been the practice of some to treat the more aggravating symptoms as they presented themselves, leaving nature to cause an absorption, or degeneration if you choose. Others applied astringents, some used the cautery puncture and many amputated the offender with some form

of tonsillotome, which afforded relief in proportion to the amount removed; the process being aided by lack of adhesions and the skill and care of the operator. Knives and scissors have also been employed in partial removals. I might here state that it is impossible to do extirpation by the common tonsillotome, as it is designed to partially protect the tonsil. If separation from the pillars is neglected, it is even less effective. While in a purely obstructive uncomplicated tonsil, partial removal has given relief, there have been more complicated conditions where no improvement took place, and in some instances they were even worse. Topical treatment did little good other than to cause temporary relief. These more or less illogical measures are still carried out to a great extent to-day, but during recent years many prominent operators have advised and practised the complete removal of the faucial tonsil in its capsule. That this cures tonsillitis is naturally apparent. Any form of operation which does not remove the diseased crypts down to their origin in the tonsil base, is very apt to be a failure. Assuming that a patient possessed an encapsulated tumor situated between two muscles in some other part of the body, who would consider it good surgery to simply snip off the most prominent portion possible, including some of the surrounding normal structure? At one time I used the tonsillotome with much vigor and enthusiasm. In some cases the removal of the obstructive element of the organ with possibly an associated adenoid gave thorough satisfaction. In others typical tonsillitis would appear at the spot where no tonsil was supposed to be. Some rather ingenious excuses have to be drawn upon under such circumstances, and one's reputation is not enhanced thereby. Until some valued function of the tonsil has been proven I shall look upon extirpation as the only rational cure of their diseases, and shall advise it unless the exigencies of the case indicate more conservative procedure.

Comparatively painless tonsillectomy may be done in adults by local injection anesthesia, sharp or dull dissection, completed by the snare, knife, or scissors. A cautery point and forceps may be used as Dr. Pynchon has described. Many of these cases are among children or timid adults, where general anesthesia is indispensable. The operation is then far more difficult than its description would seem to indicate. I believe with others that the average abdominal section is less troublesome in its actual performance. These patients breath poorly at all times and worse under anesthesia. We are obliged to work in their principal respiratory channel and blood and mucous add to the difficulties. For many reasons a skilled anesthetist is a most important factor. A trained assistant on the opposite side of the table is essential. The dorsal or side position may be used with illumination from a head lamp or window. A mouth gag is placed in position, the assistant holds the tongue depressor and helps with the sponging. The tonsil should be grasped with suitable forceps and separated from the pillars and loosened from its bed by sharp or dull dissectors. When this has been accomplished, the organ may be removed by the snare, fingers, scissors, knife, or by other means. My preference has been the snare and it has served me well. If these measures are carefully carried out, bleeding is usually inconsiderable. If working under proper surroundings any bleeding vessel may be caught with an ordinary hemostat or a tonsil clamp may be used. An ice water douche or pressure with the fingers is usually quite sufficient. It may be argued that extirpation causes more hemorrhage than amputation. It has not been my experience nor that of others so far as I know. Whatever the technic its object should be to follow the capsule in separating and remove the structure in the shortest time according to good surgical principals.

If adenoid tissue is present it should then be removed by the cutting forcep, currette, finger, or their combined use. It has been my experience that no instrument can always be depended upon. Tufts of tissue frequently remain which could easily cause a persistence of symptoms, and which the finger nail easily removes. The respiratory process is usually improved at once, but some local soreness is present for several days. Infection and secondary hemorrhage have occurred, but usually the recovery is uneventful. To attain an ideal result, the tonsillar fossa should be cleansed at intervals by the family or nurse and the surgeon should at times apply suitable astringents to the granulating surface until healing is perfect.

In such an operation I always prefer the desirable facilities of a hospital operating room. It is an advantage to both the surgeon and the patient. In preparation the nose and the pharynx should be well cleansed, the bowels evacuated, urine examined, and the general physical condition investigated. Subsequent to the operation it is important that the patient remain in his room over night and if all is well on the following day more freedom is allowed.

Owing to the vogue of the tonsillotome such operations will be considered trifling by many. Such a view is distinctly erroneous and should be discouraged. The object to be attained is very important. The operation is a major one and a proper compensation should be exacted in all cases except where charitable consideration properly applies.

THE USE OF TUBERCULIN IN OPHTHALMIC PRACTICE.*

By LUTHER C. PETER, M.D.,

PHILADELPHIA.

In view of the numerous contributions on the subject of tuberculin which have appeared in medical journals during the last year, one hesitates to add anything of a personal experience lest it be but a review of what has been well and carefully covered or perchance may add to the confusion and uncertainty as to the real value of tuberculin. The aggregate of personal experience, however, furnishes the data by which we may form a true estimate of its value and dangers. There is a note of warning in most of the more recent papers, as to the dangers which may attend the use of this agent, and it is largely because of the dangers to the eye in particular that I present this subject from the standpoint of an ophthalmologist.

As in the application of new ideas and new remedies, there is a reaction from radical enthusiasm to almost complete nihilism, so tuberculin has passed through its evolutionary period and the profession is prepared to estimate it at its true worth.

The untoward complications and unsatisfactory results observed in its use as a diagnostic and therapeutic agent, I believe, are due to faulty technique and to a lack of discrimination in the selection of cases and of methods, and although the personal equation must enter into the minor details of the

*Read before the Northwestern Medical Society of Philadelphia.

technique, there are certain broad rules which, if followed, will avoid the mistakes of the past and will furnish more uniform results in the future.

As a diagnostic agent, from an ophthalmic point of view, the Calmette reaction has little to commend itself in determining the character of lesions and diseases of the eye. This assertion is rather dogmatic, but is warranted by my personal experience and I believe is borne out by the numerous contributions of ophthalmic surgeons in general. The possibility of causing serious damage by a single application to an eye which may be the seat of even a low-grade conjunctivitis, or to a perfectly healthy eye by repeated instillations, has been fully demonstrated to every one who has employed this test. These results may be obtained in an eye which is not the seat of tuberculous processes and, therefore, in addition to the dangers, there is an element of uncertainty added which largely nullifies the value of the test. The natural inference, therefore, is that the Calmette test should not be used in determining eye conditions. I wish to emphasize this conclusion because we have other and better methods of application without the risk of serious injury which may attend the ophthalmic test.

In its application to determine the tuberculous or non-tuberculous character of lesions in other parts of the body, the reaction has several points of advantage, if the experiments are conducted under the following conditions:

1. The application should be made only by an ophthalmic surgeon because the greatest care should be exercised in determining that conjunctiva and lacrymal sac are entirely free from disease.

2. Solutions of one-half per cent. to one per cent. of old tuberculin should be the maximum strength employed.

3. Not more than two instillations should be made, not only because unnecessary to obtain results of real tuberculous reaction, but because a protracted catarrhal conjunctivitis is not infrequently the sequel of repeated instillations, even in an eye which is not tuberculous.

The advantages of the ophthalmic test over the cutaneous and subcutaneous reactions, when employed under the above conditions are:

1. The ease with which the test can be carried out, because of the accessibility of the parts treated, the usual ready cooperation of the patient, and because there is no need for a careful observation conducted in an institution which the subcutaneous test requires.

2. The absence of a constitutional reaction.

3. The determining of active processes as contrasted with the cutaneous and subcutaneous reactions which are more apt to reveal latent foci of disease.

4. The unmistakable visible evidence of a positive reaction as against a possible doubt in the cutaneous test, when the scarification process is used, and the doubt of a subcutaneous test if the reaction is not well marked. The ophthalmic reaction when positive is rarely doubtful in appearance.

There is, therefore, a distinct though limited field for the application of the Calmette reaction. Its value, however, lies only in obtaining positive results, for failure of even a second instillation may be followed by a successful von Pirquet or subcutaneous demonstration of latent foci of disease.

To determine the character of ocular lesions the cutaneous test of von Pirquet may be employed, but if negative a hypodermic injection of a small dose of tuberculin should be used. The von Pirquet test is fairly reliable, but the conviction is growing that after all the subcutaneous use of tuberculin in all cases which can be brought under proper observation in hospitals or at home under suitable conditions, is the most reliable and satisfactory method and the method attended by least danger if the dosage is carefully guarded. The Calmette and von Pirquet methods should be reserved for selected and suitable cases. In fact there is a great opportunity for exercising careful discrimination in the selection of cases and of methods adapted to individual cases, and I believe that the untoward results and conflicting conclusions are for the most part due to a lack of discrimination on the part of the operator and not to either the tuberculin or the method used. The misapplication of a thoroughly reliable method to an unsuitable case will lead to faulty conclusions both as to the case and the value of the method.

It is a well-known fact that many so-called tuberculous eye conditions are not instances of local disease due directly to the presence of tubercle bacilli, but rather the result perhaps of toxins or more often only a part of the general symptomatology of central diseases—evidence of lowered vitality. A constitutional reaction therefore, is most desirable, but of so mild a nature as not to cause a local reaction. One sees from time to time in literature the mention of a local as well as a constitutional reaction and it is even sought for—a practice which is dangerous and should be carefully avoided by a sufficiently small dose, *e. g.* 0.005 mg. of the solid tubercle bacilli. Should a reaction fail to occur, a larger dose may be administered with safety but the initial dose should always be small. The demonstration of a constitutional reaction in a case of suspicious local disease is strong presumptive evidence that the local trouble is a sequel of central disease and a local reaction is therefore rarely necessary and should not be sought.

In the treatment of tuberculous eye conditions by therapeutic doses of tuberculin or tuberculous preparations, there is opened up to us a new and most promising field, fraught, however, with dangers throughout the course unless the greatest care is observed as to details. Hospitals naturally furnish the ideal surroundings for this work, but since it usually covers a period of three months or more, intelligent cooperation in the home or in one's office, will yield equally good results.

A three hour daily temperature record should be kept on a graphic chart if possible, pulse and respirations likewise. On this chart can be recorded the time of administering the tuberculin and the dose employed. When carefully kept, a glance at the chart will tell one the result of the treatment. In my private work, I instruct the patients to mail to me a daily postal-card record of the temperature and pulse when possible, and such comments as to their condition as they may see fit to make. These data are absolutely necessary to obtain good results and to avoid doing harm. Carelessness in the minutest detail will sometimes cause failure or, what is of more vital importance, will do harm.

The initial dose should not be over 0.0001 mg. of the tubercle bacilli and in children 0.00001 is better. If no reaction follows, the same dose may be given the following day, but if a reaction follows, several days should intervene before a second dose is given. A subsequent dose should never be given throughout the entire course of the treatment until all evidence of reaction have passed. This is es-

pecially important when the dosage is gradually increased. My preference in the selection of tuberculin, because of its constancy, has been von Ruck's watery extract, a 1 per cent. solution known as Sol. No. 100. From this I make four dilutions. Sol. No. 10 consists of 1 c.c. of No. 100 and 9 c.c. of diluent, which is 0.4 per cent. phenol in physiological salt solution. A second solution No. 1 consists of 1 c.c. solution No. 10 and 9 c.c. of diluent. A third dilution Sol. No. 0.1 consists of 1 c.c. of Sol. No. 1 and 9 c.c. of diluent. A fourth dilution may be made if necessary for children. These are the dilutions that are made according to von Ruck's instructions.

The initial dose is 0.1 c.c. of solution marked No. 0.1 and sufficient diluent, possibly 0.5 or 0.6 cubic centimeters; this 0.1 c.c. represents 0.0001 mg. of the solid bacilli. If this dose is tolerated I increase the daily dose 0.1 c.c. at a time until 5 c.c. has been reached and continue the same dose for several days, gradually increasing to 0.9 c.c. When this point is reached, this dilution is discarded and the Sol. No. 1 is employed in the same manner. By this very gradual and definite increase in the dosage a tolerance is gradually built up and reactions are rare. When they do occur several days should elapse before another dose is given and the dosage should not be increased for several days thereafter.

I have gone into these details so that those who are just beginning to use tuberculin may profit by my mistakes.

As to results:

(1) I have not seen any unpleasant symptoms and have not seen any harm done by following this method.

(2) Some days before one notes any change for the better in the local conditions, certain constitutional changes make their appearance. The appetite returns or improves, especially in children; cough, if present, abates, the patient takes on flesh and gives unmistakable evidence of improved health. One may note these changes in the second or third week of treatment. Shortly after this general improvement, including reduction of temperature and pulse rate (if it had been increased), the local conditions improve.

A cure of local conditions is not an indication for stopping the tuberculin. The treatment should be continued until there is evidence that the central lesion is absolutely under control, although daily doses are not necessary after fairly large doses are tolerated.

Just as in the management of central tuberculosis, this treatment must be combined with the methods of to-day, namely, fresh air, rest, and forced feeding, and in addition, local measures should not be omitted. The local treatment must naturally be influenced by the conditions and parts affected.

In the selection of tuberculin, von Ruck has only recently tabulated series of cases treated by modern methods without tuberculin, with tuberculin, and with the watery extract or the emulsion. His conclusions are so concisely and overwhelmingly in favor of the latter that there seems to be little room for doubt as to the superiority of the preparations which contain the solid tubercle bacilli. The latter products yield to a more accurate dosage and to greater uniformity than other preparations placed on the market.

110 South Nineteenth Street.

NEPHROPTOSIS,

ITS CAUSE, AND DIAGNOSIS BY INSPECTION.

By MARK I. KNAPP, M.D.,

NEW YORK.

I shall begin with a brief review of my monograph of "How to see all the organs of the body with our naked eyes," which was published in the *St. Louis Medical Review* of February, 1908. The present publication follows as a continuation of the observations already described in the just mentioned monograph. To see beneath the skin with the naked eye without any assistance of any instruments sounds quite incredible, and one is inclined to believe that such sight is a born gift not allotted to every person. But every physician can learn this art if he so desire. Perseverance is all that is necessary.

Is it possible to see the outlines of all the organs upon the skin of the person? The answer is a decided, emphatic, and an unequivocal yes. Can we see all the organs in every case irrespective of the adipose layer of the skin? Yes. Obesity makes no difference, and, between the moderately fat person and the very fat person, the very fat person shows the outlines better, contrary to what by theory is assumed. What element is absolutely essential for us to see the outlines of the organs upon the skin? Respiration.

Every physician should learn, whenever possible, to rely upon himself, upon his own powers of hearing, touch, and sight rather than upon instruments. Every physician should strive to the best of his ability to perfect himself in observation of the patient's every move and every expression. Practice makes perfect. There is nothing without cause; ascertain the cause of every phenomenon; there is no chance, there is no accident; under like conditions the like invariably results. We must always look for symmetry in the two halves of the body and any variation must be explained. Every unevenness, every elevation, every groove, every depression, every moving shadow upon the skin has its absolute cause, and must be recognized and interpreted by the physician.

These are the cardinal principles: (1) The skin adapts and molds itself in accordance with the subjacent organs, thus presenting to the trained eye elevations, depressions, ridges, and furrows; (2) all organs move with respiration; (3) the movement of the skin due to the respiration is perpendicular to the movements of the viscera. The axis of motion of the skin is transverse to the body while the action of the motion of the viscera is longitudinal. Because of these physical facts the gliding of the organs beneath the skin can be seen when we have present proper illumination and the proper position of the observer. Light of medium intensity—diffused daylight or artificial light—is essential; too strong artificial light or direct sunlight must be avoided. The observer must stand a certain distance away from the patient so that his line of vision will fall obliquely upon the region to be seen. If the observer will now bring his eyes to the level of the patient's skin, he will see certain lines move beneath the skin. His knowledge of the anatomy of the region will teach him what organ the line seen represents.

The acquiring of the art of seeing beneath the skin is not only a matter of self-satisfaction, but infuses confidence in the patient and his friends who

happen to be around. It is not always that the patient has a ready-made history for us. Often he comes to tell us only that he feels weak and does not know what is the matter with him or concludes his history with one or two symptoms. Imagine what hold one gains over the patient if the physician is able to tell the patient many a symptom which the physician knows must result from a certain condition he observes. To be concrete I will give some illustrations. The patient tells us only of his weakness. He strips and lies down for examination. We observe tremulous, wave-like movements in the region of the stomach. This signifies gas within the stomach which transmits the concussions of the heart. We conclude from this a pressure of the distended stomach against the heart, and at once proceed to give the patient the symptoms of such interference with the heart's action. We say to him: I see you suffer from palpitation and that you cannot go up the stairs very well, etc. Now, the patient never said a word about that. The patient's face brightens up wondrously, and affirms your statement. Does one doubt the effect upon the patient? Or, we see a somewhat cylindrical bulging in the lower right quadrant of the abdomen running upward and outward. We conclude that this represents a distention of the cecum and ascending colon and tell the patient, pointing with the finger to the region: I see you have some uneasy sensation, some pain in this region. And again the patient looks surprised at our wisdom. When I speak here of bulging I mean such bulging as is seen only by the trained eye. For if the bulging is very marked there will be complaint of the pain. I was called to see a lady who could not move about because of her obesity; I was to tell her what was the matter with her from simply looking at her. On hearing this I smiled; the patient stripped. Assuming the necessary position I saw a certain elevation upon the skin of her abdomen. I approached her and began to palpate over that spot. Why, doctor, exclaimed the patient, this is the very spot that has given me pain for so very long, and I was always told that there was nothing the matter there. The result was that I treated her, her family, and some friends of her. Lest there be any mistake I will again mention that the fat person shows the outlines exceedingly well.

After this brief review I wish to return to the subject of this paper. Nephroptosis is quite a common occurrence among women, although not exclusively belonging to women. Nor does nephroptosis always produce symptoms, nor are there always evidences of a pathological change in a displaced kidney. Sensitiveness to the touch, pain, and tenderness are not always elicited in handling the ptotic kidney; such symptoms are found quite often. Speaking of nephroptosis, let me consider the alleged causes. I have been taught that nephroptosis is produced by tight lacing, by pregnancy, and, in the male by, well, here it is a reflex phenomenon, most likely. So long as I had no skill in palpation I accepted the teaching. But after I had learned how to palpate under the masterful personal tutorship of Kuttner, Ewald's assistant, and then was able to find nephroptosis not only in females but also in males, not only in the grown-up but also in the infant I found it impossible to reconcile the teaching with the facts. The fact that nephroptosis is found in very young infants—and I have seen and demonstrated many such cases—necessarily induced me to search for the origin of nephroptosis at a very early date when neither of the reasons at present accepted can possibly operate.

Anatomy teaches that the kidneys are held in place by thin, loose areolar tissue and some fat. As is well known the resistance of such binding material is not very great; it will tear with comparative ease. Thus the attachment of the kidneys differs from the ligaments and mesenteries of the other organs. In comparison the kidney is a very heavy organ held in place by a very flimsy means. Should the kidney be pulled, but very slight resistance is experienced; the ease with which the kidney is shelled out is known even to the ordinary housewife. It is immaterial whether the kidney is pulled out or is being catapulted; in either case the mooring of the kidney is too weak to offer effective resistance. And, should the comparatively very heavy organ be catapulted, the areolar tissue would very easily break and the kidney leave its normal site or rather be thrown from its normal site. This catapulting force within our body is produced by the centrifugal force. All organs within the body are movable, their motility being limited by the extent of their attaching medium, *i. e.* by the stretching point of their ligaments. Whenever the body is suddenly projected in either a verticle or a horizontal direction the movable organs within the body are thrown in the opposite direction by the centrifugal force. We feel that when we are suddenly raised or lowered in an elevator or whenever the motorman of an electric car suddenly releases all the power. Often the organs and vessels are thereby torn or bruised or their attachments are torn and bruised. Having these physical laws before us, how can we apply them to explain the cause of nephroptosis? It stands to reason that, if we can find physical laws to be responsible for nephroptosis, then we can readily see why males and females, young and old can have it. In accordance with the statements just made, if we could find that the body is at any time being projected forcefully or violently so that the centrifugal power would come into play then we could find the cause of nephroptosis. We do not have to dig very deeply for such facts. Such facts are known to all of us. We see them in the method a good many have of showing their joy over infants. The fond father, the fond mother, the happy family or the loving friends in their exultation throw the baby in the air. This procedure is often repeated, during which the kidneys are gradually loosened; the centrifugal force comes into play and catapults the kidneys away from their attachment, a little every time. What adults feel when shot down or up an elevator also happens in the infant. If we assume the truth of this theory we can explain nephroptosis in every case, male or female, old or young. The rope jumping of children which has claimed many a young life thus reveals and explains its danger.

The normal kidneys can be seen about one inch away from the spine and about two inches above the crest of the ilia. An oval-shaped body, one by one and a half inches in diameter, can be seen to recede with inspiration and come down suddenly and with a jerk at the end of expiration. If the kidneys are not present at that location, if there is nephroptosis such a phenomenon is absent and there is a hollow to correspond. It is this hollow that we can see, and whenever we see that hollow we can make the diagnosis of nephroptosis. The method

which I wish to bring out now differs from the one just mentioned and which appeared in my first monograph. My present method is to stand in front and close to the side of the patient, then bending down the head to the level of the patient's hip to bring the eyes to the plane of the patient's spine. I now observe the profile of the skin over the outer border of the longissimus dorsi muscle. In the normal body with the kidneys in the correct situation the line of the profile I see slopes down gracefully over the buttocks. The line runs down vertically, straight from the last rib to the region of the level of the crest of the ilium and then over the buttocks. But in nephroptosis the profile shows a bending in, a concavity at the level of the crest of the ilium.

A distended bowel may, however, partially or entirely obliterate that depression. If we place the patient on the back we will invariably see an elevation on the right side of the abdomen, its location corresponding with the location of the displaced kidney. This elevation upon the abdomen is seen now higher and again lower in different subjects and in different degress of nephroptosis. This method of diagnosis of nephroptosis by inspection applies to females; I am not yet satisfied that it applies as well to the male owing to the different anatomical construction of the pelvis.

In conclusion, I again ask that the profession take up the matter and attempt to learn, by practice, the art of seeing beneath the skin. I am sure that every one who so desires will gradually acquire that method of seeing beneath the skin which is not magic, is no superior or superhuman gift; it can be quickly learned by every physician and it is well worth our efforts.

"LETTERS TO A NEUROLOGIST."

SECOND SERIES.

By JOSEPH COLLINS, M.D.,

NEW YORK.

PHYSICIAN TO THE NEW YORK NEUROLOGICAL INSTITUTE.

I.

Dear Doctor: I am bewildered. A few weeks ago I read in the paper an interview with one of your profession which set forth that alcohol in any form is not only injurious to the consumer, but that it entails disaster of some kind upon his descendants. A few days later I read in a magazine an elaborate article, by a physician, in which it was stated that alcohol is injurious even when taken most temperately, and that such use of it, even though not habitual, causes dreadful diseases, cruelly and effectively handicaps the drinker in the struggle for livelihood, stultifies his efforts, undermines his moral sense, accentuates his weaknesses, exaggerates his limitations, debases his character, curtails his effectiveness as a member of society, dwarfs him in his resemblance to his Creator, and unfits him for the honor in which he takes most pride, viz., to reproduce his kind. In brief, such indulgence emasculates him physically, mentally, and potentially. Yesterday I read a symposium on the subject in the Sunday *Planet*. From this I gather there is no unanimity of opinion on the part of authoritative writers, but the preponderance of evidence is that the temperate and non-habitual use of mild alcoholic beverages is not injurious to one's minds, morals, or descendants. Then I got interested in earnest and I devoted my evenings to scientific journals in which are set forth the results of deliberately planned and carefully conducted experimentation by physiologists and psychologists. The bewilderment that I have mentioned soon followed. I really do not see my way clear to advise my own son, who you know has just entered the Law School of ———— University, or what to do myself in regard to taking stimulant. Ever since we were in college together, I have taken, as you very well know, a small quantity of one wine or another with my dinner, and occasionally I have taken spirits. I am not dependent upon alcohol, so far as I know. That is, I mean to say, I could get along without it, just as I could get along with a smaller house, or one less servant, or one overcoat. But I prefer not to do any of them, for to do so would cramp my comfort. It would add a little friction to my life which I choose to avoid, and so long as my conduct in this respect does not encroach upon the rights or joys of others, why shouldn't I do as I am doing? Now that, is just my position about taking stimulants as I take them, and practically this is the point of view that I have tried to give my children. When Roger went to Concord to school, I told him that the assurance that he would not touch intoxicants before he graduated from college would give his mother more happiness than anything in this world, and also that I was convinced that if he would so abstain, not only would he not regret it, but that later in life when he had to assume the responsibility of steering the ship of life for others, he would hold this action one of his most valued possessions. I have every reason to believe that he did not know the taste of beer, wine, or spirits until this summer, when he took it at our table, and with the entire approbation of his mother and myself.

There is no more temptation for young fellows to drink in dear old ———— than there was when we were there twenty-five years ago, and were it otherwise, I hope Roger would still have exercised the same self-control. Now it is an entirely different matter. He has reached the age of decision and discretion. He is beginning to associate with young men who will be his peers and competitors in his chosen profession. The impression that he makes upon them now will endure throughout life, and it is similar to that he will make upon others with whom he comes in contact when he goes out into the world to win his way. I want him to be virile and poised as much as I want him to be courteous and modest. I don't want him to be thought a mollycoddle or to develop any vestiges of sanctimoniousness. A young man who is a total abstainer is to my mind a marked figure. When I encounter such a one, unconsciously I register a judgment that either he is a reformer or a weakling, and as I have a prejudice against the one and a pity for the other, no doubt I often do him an injustice and obstacle myself to a desirable intimacy. I want to have my boy spared such judgments.

But here is the crux of the matter. If this boy's health and usefulness and most obvious purpose is going to be shattered, impaired, and negatived by temperate consumption of those fluids that contribute to comfort, well-being, and *joie de vivre*, I should like to know it, for I feel that I am under pressing obligations to inform him convincingly concerning it. Moreover, if it is so, my own conduct is most reprehensible. In the first

place, I wish to avoid any such scene as Stephen Phillips depicts in the question,

"Why is my body then so weak?
Why do I falter in the race
And flag behind this mighty pace?
Why is my strength so quickly flown?"

and secondly, I am not keen on laying up for myself countless nights of pain and endless days of misery. So far as my drinking impairs my mental efficiency or encroaches upon my capacity to discharge my duty to the community, I don't need counsel. The use of alcohol may "diminish the intellectual functions by dulling the creative faculty, impairing judgment, vitiating the correctness of perceptions, and by generating timidity," as one of your confrères recently stated in the public prints, but until he or someone else proves it, I choose not to believe it, in the same way as I choose not to believe that Mars is inhabited by man, that disease does not exist, that there are more than five senses, much assertion to the contrary notwithstanding. I may not be the best judge, but I am an adequate judge, and I don't concede that a scietific investigator or solicitous neighbor has any right or justification to concern himself about these matters. If my conduct or mode of life entails pain or penalty to others, even though they are remote from me or my time, I want to know it, that I may compensate or indemnify, and give earnest of my regret so far as it is still within my power to do so. Therefore I turn to you, dear old friend and fellow-playmate, for orientation. I think I deprecate the curse of alcohol as much as anyone, and I appreciate what is meant when it is referred to as the bane of humanity. I know your views on this aspect of the subject and I am not asking you to reiterate them. What I want is a plain statement of the effects of the moderate use of alcohol upon the average adult. You may assume that I know that what is moderate for one man is excessive for another, than one man's meat is another man's poison; that we can do with impunity at twenty that which would be recklessness at fifty, etc. The one thing that I ask you not to assume is that I believe any statement of a zealot when not supported by positive proof. Statistics in the hands of total abstainers are, in my judgment, not necessarily appropriate material for the deduction of facts.

Yours affectionately.

Dear Paul:—I could answer your letter very briefly. There are no real facts founded on scientific investigation to show that the habitual use of alcohol in small quantities is dangerous to the adult consumer, or perilous to his descendants. I judge, however, that you do not want dogma, therefore I am going to reply to it in some detail and you can draw your own conclusions. You know what metabolism is, I have no doubt. It is the equivalent of all the chemical processes that go on in the human body. Metabolism is life—anything that interferes with metabolism interferes with life. When taken beyond a certain amount, alcohol interferes with metabolism; therefore it becomes all-important to know approximately what the amount is. The best advice at present would seem to be that furnished by Prof. Abel of Johns Hopkins University. The limit that is physiologically permissible is from two-thirds to three-quarters of an ounce of absolute alcohol; that is, one-half pint of champagne, one and one-half ounces of whiskey, or two to three glasses of beer. This is less than one-half the amount which has usually been considered safe for an adult to take in 24 hours.

I maintain that the question "Is alcohol a food?" is not germane to our discussion, even though so much is made of it and even though it permits the brilliant rejoinder, that if it is, it is a poisoned food. Let us grant that it is a poison. Is that any reason why we should not take it, if our intellect justifies us in so doing? Are not drinks and articles in common use poisonous? We do not hesitate to use strychnine and arsenic and mercury day after day for months and years although they are poisonous. The question is, can they be utilized to the advantage of the individual or to those who come into any relationship with him? I do not recall that any great amount of energy has been expended in endeavoring to find out if tobacco is a food; or if theater-going is an ailment, or if listening to music increases our oxidation. The question is, Does indulgence in one or all of them make life more worth living than it is without them? Their non-injuriousness being assured, there seems to me rather a general unanimity of belief on the part of those who have had experience, that temperate indulgence in the cup that cheers and likewise inebriates, contributes materially to the joy of living, smooths many rough places, cheers many despairing minds, and brings respite to many sorrowing souls. It likewise lightens the terror of many painfully prosaic and commonplace experiences of life, such as residence in the suburbs and commuting to the city, discharging domestics, moving day, etc. Nor do I gather from your letter that you wish to know from me whether or not alcohol is a real stimulant. You know, as well as I do, that it causes the individual who takes it to feel stimulated. Whether or not it is a physiological stimulant in the strict sense of the term remains to be determined; it certainly deadens fear, dispells apprehensiveness, and puts to flight morbid thoughts. It therefore displays itself in the garb of stimulation. That the majority of my profession think it is a real stimulant is amply indicated by the reports of practically all the hospitals in Christendom, in which the expenditure for alcoholics is a very considerable item.

"Alcohol has no place in the economy of nature," says one recent fanatical writer. If it is not one of Nature's economies to contribute to the happiness and well-being of her most advanced product, she is a spendthrift stepmother. "Alcohol stamps out initiation and interferes with creative thought," says another, but because von Helmholtz could not think so effectively or so creatively after he had taken small quantities, it does not follow that Smith or Jones cannot; in fact, both you and I know many of the Smith and Jones family who never have creative thoughts except after they have taken alcoholic stimulant.

It is probable that no one questions the fact that the intemperate use of alcohol is directly and indirectly a potent cause of insanity, imbecility, and illegitimacy, any more than one contends that mankind would be vastly improved physically, mentally, and morally if alcohol were taken out of the world. To satisfy the appetite for food is commendable and salutary, but to eat like a beast of the

forest until capacity is taxed, is fraught with danger to health and prejudicial to morality. Scrupulosity and veracity are qualities that adorn a character, as precious stones adorn a crown, but morbid scrupulosity and the New England conscience are the Scylla and Charybdis upon which many a fine character has foundered in its endeavor to get from a landlocked harbor to the open sea and plain sailing.

It means nothing to me, and I have no doubt it is equally meaningless to you, to be told that out of 25,000 idiots, imbeciles, and epileptics in the Bicêtre Hospital in Paris, 41 per cent. were of drunken parents, save that 51 per cent. of them had parents that were total abstainers! So much the worse for them. Moral: Don't be a total abstainer. Of course this is *reductio ad absurdum* with a vengeance. Anyone who amounts to anything cannot be frightened into abstaining from alcohol, and if he is not such a person, it isn't worth while. So far as any real incontestable facts exist to show that the so-called idiopathic nervous and mental disorders are caused by parental alcoholism, it is my belief that they do not exist. Furthermore, I do not believe that anything is to be gained by the use of statistics as they have been collected in the past. "Alcohol is a potent factor in the causation of nervous and mental diseases," is a statement that is frequently encountered in medical and lay writings. But aside from one nervous disease, multiple neuritis, and two or three well-defined varieties of insanity, there is not the slightest demonstrable evidence that such a statement is true. The same may be said of most, possibly all, of the organic diseases attributed to alcohol, such as arteriosclerosis, cirrhosis of the liver, diabetes, gout, obesity, etc. It is quite as easy to prove by statistics that chronic alcoholism has nothing to do with the causation of arteriosclerosis, as it is one of the commonest causes of it. I don't want you to think this is my say so; I refer you to the article by Cabot.

I believe with Kraepelin and his pupils that alcohol in small quantities for a considerable length of time diminishes all form of mental activity, but sometimes it is a very desirable thing to diminish mental activity. It is always diminished in reverie, oftentimes in meditation, two of the most pleasurable experiences that in man alone is permitted. But just because ten hours of sleep is gratefully received once a fortnight or year, it doesn't follow that it would be desirable and beneficial to have it every night. Zealous advocates of total abstinence have recently tried to make propaganda out of this work of Kraepelin's, for it is based on laboratory tests and accurate measurements. Alcohol kills the creative faculty, they say, then they help memorialize Poe and seriously discuss whether he or Hawthorne shall be called the premier of American letters. It impairs judgment, they say, yet the man of this country upon whose judgment time is setting the seal of approbation more conspicuously as the years go by took alcohol temperately, and at times, it is said, intemperately. "It vitiates the correctness of perception and generates timidity," but the greatest general of the Civil War didn't display any particular incorrectness of perception or timidity. If I were to make a list of all the great writers and creators or thinkers of the past or the present, who used alcohol habitually, you wouldn't notice any conspicuous absentees the first few times you read it. Would Burns have written more soulful lyrics if he had not drank, or would Charles Lamb's memory loom up more imperishably or would Oliver Goldsmith's niche be above Shelley's if he had not consumed more ardent spirits than the latter?

How absurd it all is! To publish yourself an advocate of total abstinence, to endeavor to convert persons to your views by intimidation is to publish yourself a crank and a fanatic. Most well-balanced persons are keen to learn what may contribute to their prosperity and well-being, and on being appraised, they conform their conduct accordingly.

Health and happiness encompass the desires of the average individual. The former often exists without the latter, but a considerable degree of health is necessary to the average individual if he is to be happy. Hence the necessity of avoiding those experiences that rob us of it. That alcohol does so when taken in excess, and particularly when taken steadily, is universally admitted, but that it does so when taken temperately and at irregular intervals most persons competent to judge deny. No one has the opportunity of witnessing the baneful, pernicious, and injurious effects of taking alcohol that the physician has, and probably few physicians maintain that the use of alcohol except on special occasions is beneficial to health. The physician's work soon teaches him to recognize limitations, and to see things as they are. Consumption of alcohol is well-nigh universal, and from time immemorial, whenever man has had the chance, he has had recourse to it as an adjuvant to every pleasurable indulgence and undertaking, and this condition of affairs is not going to cease under the influence of fanatical cries from the housetops about the injuries that temperate consumers of it are doing themselves. The way to bring about reform is by education, not by fright. The teachings of the past concerning hell retarded the progress of the Christian religion, and nowadays reference to it as a deterring factor to immorality is, I fancy, not considered very effective even by the most orthodox. You can't intimidate pleasure-loving man by threatening him with possibilities of pain. We can reason with him, however, and if our reasoning is sound, we can convince him. In other words, we can educate him. It is generally conceded that the plastic period of youth is the time when education is most easily acquired. My belief is that Roger needs only to be appraised of the dangers flowing out of the abuse of alcohol, and he will warn himself. Certain it is that if he doesn't contract the habit of becoming dependent upon alcohol for any purpose, emotional or physical, during the next ten years, he won't contract it at all.

As for yourself, you don't need advice, but I have great pleasure in referring you for encouragement in your conduct to one Quintus Horatius Flaccus, who I recall shared with me the intimacy of your youth, and whose lines,

> "Ille potens sui
> Lætusque deget," etc.

I have often heard you quote, even in the days when you were not so conspicuously adorned with the "mens æqua" as you are now. In Ode XXI you will find him thus apostrophizing his Wine Cask:

"You lend a gentle stimulus to minds 'tis hard to stir, you reveal by cheering wine the cares and secrets of the wise; to minds perplexed you hope restore, and to the poor man give both strength and power, for after you he fears not threatening crests of angry kings nor soldier's arms."

Devotedly yours,

New York, January 1, 1910.

THE FIRST GUN OF THE ANTIVIVISECTION CAMPAIGN.

THE antivivisectionists so-called, that is the misguided, the ignorant, and the fanatics who have no objection to live-broiled lobsters, "live feather" pillows, spring traps for mice, sticky fly paper, and other forms innumerable of torture of the brute creation, but shudder at the use of animals for the manufacture of vaccine and antitoxins or for the gaining of knowledge that will aid in saving human life, have opened their annual campaign by an attack on the Rockefeller Institute. A newspaper of this city, whose proprietor is said to have a reason, though no excuse, for disliking medical men, has begun the publication of affidavits from discharged employees of the institute, picturing the "horrors" of animal experiments, particularly the epoch-making experiments of Carrel on blood-vessel anastomosis and the transplantation of viscera and other parts. It is made to appear that these are revelations of the secrets of the torture chamber, though all that these persons have to tell has already been told time and again in reports to societies and in the medical and other scientific journals, and even in the secular press. Among the horrors mentioned is that the experimenter after grafting a leg on a dog "twisted" it to see if the bones were knitting, and the impression intended to be conveyed is that the limb was turned round and round provoking howls of agony. An experimenter, no matter how "cruel" he was, would not be so foolish as to vitiate his experiment by breaking up the adhesions in this senseless way, and what he did, if he "twisted" the leg at all, was what every surgeon does with a fractured bone to assure himself that union is taking place. Another harrowing detail is that the dogs, when operated upon, under an anesthetic it is admitted, lost more or less blood. Still another is that when one of the operations failed and the dog was in pain he was chloroformed at once so that he should not suffer. And so with all the rest of this well-paid-for matter. The head lines are horrible, but any one of moderate intelligence, reading the affidavits and noting the character of the experiments and that they were always done under anesthesia, can see that they were conducted with no more "cruelty" than any surgical operation on man or beast. Many columns of equally hideous and bloody details could be written from the account of a scrubwoman or a day laborer who was allowed the run of the operating room and surgical wards of a hospital for a day or a week; and the surgeons who were racking their nerves and wearying their flesh in the endeavor to relieve pain and save life could with equal effect be called butchers in the stirring head lines.

In commenting on these "revelations" the *Herald* says that "no important discovery or improvement results from these tortures," which is, of course, untrue, and should have been known by the writer to be untrue. In a hearing on one of the antivivisection bills before the New York Legislature a physician told of the saving of the life of his child by an operation which would have been impossible without these very experiments at the Rockefeller Institute. A very large part of modern medical science is indeed based upon the knowledge gained by experiments upon animals, which could not have been gained in any other way. Diphtheria, tetanus, cerebrospinal meningitis, infantile paralysis, and many other scourges of mankind have been or are in course of being shorn of their terrors as a result of animal experimentation, many life-saving drugs have been given to the world by the same means, and the science and art of surgery might as well have been left to the barbers had animal experimentation been impossible. Millions of animals, birds, and fishes are tortured and slain every year to provide food, clothing, and mere sport for mankind, and the zoophilists say nothing; but when a few hundred or a thousand animals are sacrificed for the sake of knowledge that will save the lives of countless children and avert destructive epidemics, a cry of pain goes up, and the lawmakers are prayed to arrest the progress of medical science. They will not do it, of course, they cannot do it, for the great mass of humanity is sane, but the periodical agitation against animal experimentation is none the less distressing to the lovers of their kind. It is inevitable, we suppose, so long as there are ignorant and unreasoning people in the world, and we are not sure that it is not useful, for it provokes discussion and is the incentive to a campaign of education. Lincoln's faith in the common sense of the common people was founded upon his knowledge of them and is ever justified. The people need but to be instructed, to learn the facts, and to be shown the results of animal experimentation, and medical science will not be thwarted in its labors for humanity.

THE ROLE OF FATS IN THE TREATMENT OF DISORDERS OF THE STOMACH.

IT used to be thought that those who suffered from dyspepsia, or from any form of gastric trouble which induced undue acidity of the stomach, were better without the ingestion of fat, except to quite a limited extent. However, within comparatively recent times this theory has been overturned, or if not completely overturned, viewed with a considerable amount of doubt. In alluding to fat in the treatment of certain gastric disorders, the substance is not referred to as an article of diet only, but also as the basis of

a therapeutic régime designed to produce a definite remedial effect on the disordered secretory activity of the stomach and, as pointed out by F. Craven Moore and R. L. Ferguson (*Lancet*, December 11, 1909), based upon the recognition of the frequency with which excessive secretory activity of the gastric glands obtains as a pathological condition, and on the demonstration of the depressant action of fats on the activity of normal gastric secretion.

Penzoldt was one of the first to confirm in some degree the suspicion long held that the presence of fats in the stomach interfered, in an unknown way, with gastric digestion. He observed that a mixture of coffee and cream yielded a lower acidity of the stomach than coffee alone. Ewald and Boas, at a later date, proved more conclusively that the addition of bacon fat to the test breakfast, with which their names are associated, resulted in a prolongation of the period of gastric digestion and a marked diminution in the amount of free hydrochloric acid in the stomach contents. These observations did not favor, at the time, the employment of fat as a therapeutic agent in the treatment of disordered secretory activity of the stomach, for the belief was prevalent that the administration of fats in gastric disorders, and especially in those of the acid dyspepsia type, was contraindicated, because it was deemed that they would induce further depression of functional activity, and perhaps be the means of providing a source for the harmful acids themselves.

The German school showed the fallacy of these beliefs, and demonstrated the fact that in acid dyspepsia the ofttimes excessively high acidity of the stomach contents was not due to organic acids, but to an abnormally high content in hydrochloric acid itself. The foregoing view of the disorders of secretory activity is perhaps that now most generally held, although it must be allowed that belief in the acid dyspepsia of organic acid fermentation is by no means dead, but is still the conception of the matter by many well-known authorities.

The new theory owes much to the investigations of Pavlov and his fellow workers, who have placed it upon a more accurate basis and have likewise thrown out valuable suggestions as to the treatment of disorders of functional activity. The workers in the laboratories of Pavlov seem to have established by their observations that liquid fats, olive oil and cream, are devoid of any stimulating influence on gastric secretion when introduced directly into the stomach of the dog, and that really their presence exerts an inhibitory influence on the normal energy of the secretory process excited by other food stuffs. Subsequent to these demonstrations with regard to the dog, some European investigators employed liquid fats in the treatment of morbid conditions of the human stomach which were associated with hyperacidity of its contents. Cream and butter were first used, then almond oil, and lastly pure olive oil. The outcome of this treatment is said to have been so satisfactory that the method well-nigh attained the dignity of an "oil cure." Drs. Moore and Ferguson, by their own observations, confirmed the beneficial nature of this mode of treatment. Cohnheim was one of the first to advocate the employment of pure olive oil, and on the appearance of his paper on the subject Moore and Ferguson tried it in a few cases with such obviously beneficial results, not only in diminishing the acidity of the stomach contents, but also in relieving the subjective discomfort and promoting the general nutrition of the patient, that further investigation of the influence of fats appeared to them desirable and they carried out a series of experiments. The oil treatment was employed in cases of gastric ulcer, duodenal ulcer, carcinoma of stomach, nervous dyspepsia, dilatation of stomach (atonic), alcoholism, and constipation. The tests were made with a plain test breakfast and an oil test breakfast on consecutive days and the results compared. The oil test breakfast was an ordinary breakfast preceded 30 minutes by one ounce of almond oil, and in the stomach contents the free HCl and the total acidity were estimated. On averaging the results in each of the several series it appeared that the greatest absolute diminution in the acid values after the administration of oil obtained in those which presented the highest average acidities with the plain test breakfast, and as appeared from a comparison of the average results in the cases of gastric ulcer, duodenal ulcer, and nervous dyspepsia, irrespective of the presence or absence of any lesion of the stomach.

As to the peptic activity of the stomach contents, it was found in 12 cases in which observations were made that the digestive power was diminished with the acid values, a result, according to the authors, due in part no doubt to the deficiency in HCl, but also, as shown by the dilution method, to an absolute diminution in the peptic content of the filtrate. Moore and Ferguson conclude from a clinical standpoint that their experience of the administration of fats, such as cream, butter, or almond oil, in conditions in which hyperacidity of the stomach contents have been found to exist, has shown this action of fats to be associated with a very definite amelioration of the subjective manifestations of the condition. In simple forms of hyperacidity depending upon slight degrees of hypersecretion the addition of cream and butter in abundance to the diet, with a diminution of the starches, will often suffice to remove the subjective manifestations. Almond oil is used only in the more severe types of hypersecretion, and then in doses of one ounce the first thing in the morning and repeated before subsequent meals if necessary. It is stated that in all cases oil thus administered has been well tolerated and has in no instance proved objectionable.

The oil treatment as a means of neutralizing extreme acidity of the stomach contents is founded on sound premises if the belief is correct that such hyperacidity is more frequently due to the fact that excessive secretory activity of the gastric glands obtains as a pathological condition, than to defective activity of the same. At any rate, it is certain that fats have a depressant action on the activity of normal gastric secretion, and it seems to be certain that this depressant action has a favorable influence on extreme acidity of the stomach contents, therefore, it may be argued that fats should be administered in cases in which this

condition exists. Possibly the treatment has not been sufficiently tested to warrant the advocacy of its use with absolute confidence, but in these days when nervous dyspepsia and hyperacidity of the stomach from many causes are so prevalent the method is, at least, worthy of a trial. It is simple and harmless. There is one point in the paper in the *Lancet* to which exception may be taken, and that is, that oil is well tolerated in all cases. There are, without doubt, cases of hyperacidity in which there is a distinct repugnance to oil.

PRECISION IN THE TREATMENT OF WHOOPING COUGH.

THERE are but few diseases in which the dicta of the therapeutic nihilists are justified to the degree to which they are in whooping cough, and there is probably none in which the layman is more cognizant of the ineffectiveness of medicines. The result of this is twofold, either the mother of the whooping child bows to Fate, does not call in the services of the physician, and allows the child to mingle unrestrictedly with its mates, or else the physician, on being consulted, feels that there is so little that he can do that he either does nothing or is so half-hearted in his instructions that the mother makes little effort to carry them out. It is therefore with pleasure and profit that one reads in the November issue of the *Cleveland Medical Journal* an appeal by E. F. Cushing for more care and attention to detail in the treatment of this disagreeable, dangerous, and highly contagious disease.

The first point emphasized in this article is the early diagnosis, which, in order to raise the physician above the grandmother as a diagnostician, must be made long before the first whoop. For this a careful blood examination should be made, for even in the early stage of the disease there is a marked leucocytosis with a preponderance of lymphocytes. Such a blood picture, combined with a catarrhal cough, when pertussis is prevalent, is strong evidence of the onset of the disease. When the diagnosis has once been made, the child should be put to bed, and kept there during the initial days of fever. Later, by taking the temperature each evening and again putting the child to bed and notifying the physician whenever the thermometer registers over 100° F., complications such as bronchitis and pneumonia may be discovered and treated in their incipiency. Fresh air treatment is of the utmost importance, as the preponderance of paroxysms at night is entirely due to the close atmosphere of the sleeping rooms. "The cold, fresh air of the winter night," says Cushing, "is far the most efficient nocturnal sedative for the coughs of pertussis," with which he is familiar. For this reason the windows must be kept open, or, better still, the child should be in one of the outdoor sleeping porches now becoming so popular as a part of the modern house. When the patient is up and about he should be confined to the house or grounds. Driving is allowed, but motoring, except in a slow machine, owing to the irritating effect of dust and rapid air currents, is interdicted. Running, romping, loud laughing, and screaming must be prevented, as each of these tends to precipitate a paroxysm, and, according to the writer, the reduction of the number of these is of the greatest importance, so much so that he requires that each paroxysm be recorded with care, the chart showing not only the number during the day, but the hour at which each occurred. Such a record not only teaches the general progress of the disease, but by giving valuable information as to the immediate exciting cause of the attacks, aids in correcting improper details in the régime. The vomiting may often be prevented by the child lying down for an hour after meals, by giving frequent feedings in small quantities, or by applying Kilmer's abdominal belt. The common drugs, as belladonna, antipyrin, heroin, and opium, all have their place in quieting the cough; belladonna especially being pushed to the physiological effect of flushing. They are, however, secondary in importance to the two main therapeutic factors, namely, fresh air and a precise régime.

These directions as to the treatment of pertussis contain a lesson possibly deeper than the writer intended to impart. In it we are told how to treat the case of whooping cough occurring in the family of the millionaire. A physician who has the personality and force of character which demands and obtains implicit obedience on the part of his patients and their parents, and whose practice is confined largely to the mansions of the wealthy, can easily isolate a child to its own grounds, of possibly several acres of lawn and garden, to the broad piazzas and the sleeping porches, under the supervision of intelligent mothers and a corps of well-trained and well-tried nurses. Under such surroundings the precision of details may easily be carried out and beneficial results obtained.

The lesson, however, which the paper teaches to the rank and file of the profession, is the extreme difficulty or even impossibility of carrying out such a régime in the vast majority of the cases of pertussis, occurring as they do in the tenement house districts of our large cities. No doubt, with the proper care and precision in treatment, much could be accomplished and many hundreds of the urban poor could be saved from this disease. Most of the cities, however, make no provision for the child with whooping cough. For scarlet fever, diphtheria, or measles, typhoid, pneumonia, or enteritis the portals of the public and private hospitals are thrown wide, but the poor child with pertussis is driven from pillar to post, from clinic to hospital to find all doors closed, and to return to the small, dark overcrowded rooms of its tenement house home. Let those who control our private charities and our city funds take heed of this question of the treatment of whooping cough, supply adequate institutions where fresh air and porches abound. If this is done, we may then hope, with the proper isolation and care of the children, for a decrease, not only of pertussis, but of its sequelæ, bronchitis, pneumonia, and tuberculosis as well.

Recurrences in Cancer.

The question of the cause of recurrence in cancer is not always one that is easy of solution. It may be that the operator has not removed sufficient tissue and diseased cells have remained behind, or possibly, and most probably, reinfection takes place by means of the lymphatics. If the latter is the case, how may we prevent this reinfection? There is much evidence to show that cancer cells are grafted on new soil in the course of operative procedures for the removal of malignant growths. The method of this grafting comes about through the use of the same instruments for extending the denuded area that have been employed in the removal of the growth. Another way is by contact of the operator's hands, which have not been sterilized since the early stages of the operation, during which the growth has been handled. F. Jacoulet, in the *Archives Générales de Chirurgie*, for October 25, 1909, gives some interesting illustrative cases showing how recurrence was produced by these methods in operations on the tongue. The removal of two incisor teeth to give room for the operation gave occasion and opportunity for recurrence in this location, which was previously healthy. The lymph channels are ready to take up and carry along cells that have contaminated the wound of entrance, and only a passing contact of tissues containing these cells is necessary. The preventive treatment of such grafts consists in avoiding the morcellation of the tumor during removal; in the resterilization of every instrument that has been used in the removal of the growth before it is employed in the further procedure of closing the wound or suturing the skin; in the resterilization of the operator's hands, or the removal of rubber gloves and the substitution of freshly sterilized ones after the extirpation of the cancer, before completing the operation. As small a wound as possible should be made, forceps without teeth should be used in operations on the tongue and insertion of a thread to aid in handling the tongue should be forbidden. This subject merits further study. We must not forget that in a cancer subject we have undoubtedly to deal with a special susceptibility of the tissues, and that autoinoculation is an ever-present danger.

News of the Week.

Physical Training in New York Schools.—Physical training has been placed on the same basis as other branches of education in the schools of this city. Pupils are to be graded for their physical training work, their progress or lack of progress counting in the credits necessary to graduation. This innovation has just been introduced by an order issued by Superintendent William H. Maxwell, upon the authority of the Board of Education. In estimating the ratings for graduation, the order says, the following points are to be considered: First—The effort and the success of the student to follow out the instructions in hygiene, particularly with regard to cleanliness of face, finger-nails, mouth, teeth, hair, and clothing. Second—Both the ability to assume a correct posture and the habitual posture, particularly when the student is writing or at rest, and the posture when marching, walking, or standing to recite; because good posture is an expression of vigor as well as an evidence of a correct physical habit. The ability of boys to "chin" themselves by raising their weight by their biceps and the facility of the girls in folk dances also are to count. Ability in these dances is to be determined under three heads: Memory, form, and spirit. A child who fails to receive a passing mark in physical training and hygiene will be referred to a school physician for examination and a special report on the case will be made to the district superintendent. Similar standards are to determine the progress of the student from grade to grade.

Care of Sick Immigrants.—Commissioner of Immigration William Williams has issued notice to the steamship companies saying that since they had notified his office that they would not hereafter be responsible for the hospital or maintenance charges of immigrants who on arriving are found to be afflicted with apparently temporary sickness the Government must decline to incur any expense in connection with the care of sick immigrants before they are landed. He also wrote that the Government insisted that the steamship companies were responsible for all charges, but could not be put in the position of being compelled to sue for them. The notice tells the companies that the Government will begin as soon as possible to make preliminary medical examinations of immigrants aboard ships "in order that those who are physically or mentally unfit to land under the immigration law may be detained on the vessels which brought them and not become charges on the public funds. The companies are warned that they must be prepared to have sent back to their vessels such other cases of sickness as may be discovered after the landing of the immigrant at Ellis Island; also, that if it is necessary to place immigrants in hospitals on shore for treatment the companies will be held "responsible for all expenses in accordance with the practice of the last twenty years."

Crusade Against Tuberculosis in Canada.—The following resolution has just been proposed and carried in the Canadian Parliament. That in view of the encouraging results which have come from the money already spent in disseminating information regarding tuberculosis, and of the interest which the people of Canada are taking in the question, and also in view of the great saving in life which has been brought about in other countries by practical work in this connection, the House is of the opinion that Parliament should now take more active steps to further lessen the great suffering and mortality.

Phipps Institute for the University of Pennsylvania.—The trustees of the University of Pennsylvania have announced that Henry Phipps of New York, founder of the Phipps Institute in Philadelphia, has presented to the university $500,000, to be used in the campaign against tuberculosis. The management of the Phipps Institute will be in the hands of the university trustees, and the study, treatment, and prevention of the disease will be continued in a new hospital to be erected at Seventh and Lombard streets.

Charitable Gifts.—The president of the New Haven General Hospital Society has announced a gift of $300,000 for the treatment of tuberculosis. It is understood that the aim of the hospital in accepting the gift and beginning the treatment will be to apply current methods for relieving and curing the disease rather than to pursue original research work in seeking new cures. For the present the name of the donor of the gift will not be made public. As soon as the weather will allow work will

be begun on new buildings. Some of the structures will be placed on the hospital grounds, in Cedar street, while others will probably be in the country at a higher altitude. The Lowell (Mass.) General Hospital has received a gift of $50,000, to be added to the endowment fund of the institution from Mr. Frederick Fanning Ayer of New York. By the will of the late Augusta Bechtel of Philadelphia, the sum of $5,000 is bequeathed to the German Hospital, for the endowment of a free bed in memory of the parents of the deceased, and $5,000 to the Germantown Hospital in memory of her husband.

Civil Service Examinations for the State and County Service.—The State Civil Service Commission will hold examinations on January 22, 1910, for the following positions: Assistant Bacteriologist, Department of Health, $900 to $1,200. Assistant Superintendent, Monroe County Almshouse Hospital, $600 and maintenance; open to women of Monroe County only. City Physician, Rochester, N. Y., under Monroe County Superintendent of the Poor, $200 per annum. Director of Laboratories, Department of Health, $3,000 per annum. Photographic Assistant, Pathological Institute, New York City, $720; men only. Physician, homeopathic, and physician, regular, $900 to $1,200. Resident Medical Superintendent, Monroe County Almshouse, $1,000 to $1,200 and maintenance; men only. Trained nurse, State institutions; men and women; $420 to $600 and maintenance. Water Analyst, Department of Health, $720 to $900. Woman physician, State hospitals and institutions, $1,000 and maintenance; to fill vacancy at Craig Colony. Applications should be filed on or before January 15th. For detailed circular and application blank, address State Civil Service Commission, Albany, N. Y.

Edward N. Gibbs Fund for Research in Diseases of the Kidney.—The Council of the New York Academy of Medicine desires to announce that the income of the Edward N. Gibbs fund, amounting to five hundred dollars a year, will be granted for a period of years to any qualified worker to be selected by the Council from those who may apply for its use in research in the clinical, pathological, or chemical problems of diseases of the kidney. Applications stating the qualifications of the applicant and the topic which he proposes to pursue should be sent to the Secretary of the Council of the New York Academy of Medicine, 17 West 43d street, New York City, N. Y.

The Mary Putnam Jacobi Fellowship.—The Women's Medical Association of New York City offers the Mary Putnam Jacobi fellowship of $800 available for post-graduate study. It is open to any woman graduate in medicine. The fellowship will not be awarded by competitive examination, but upon proof of ability and promise of success in the chosen line of work. Applications for the year 1910-11 must be in the hands of the committee on award by March 1, 1910, and must be accompanied by: 1. Testimonials as to thoroughly good health. 2. Letters as to ability and character. 3. A detailed account of educational qualifications. 4. A statement of the work in which the applicant proposes to engage while holding the fellowship. 5. Examples, if any, of her work, in the form of articles or accounts of investigations which she has carried out. When possible it is considered desirable that the applicant should present herself in person to the committee. Two reports will be expected from the holder of the fellowship, one to be presented about the middle of the work and a detailed report upon its completion. As a rule, the fellowship will be awarded but once to an applicant; in case of unusual ability a reaward will be considered. All applications for this fellowship should be forwarded to the chairman of the committee on award, Emily Lewi, M.D., 35 Mt. Morris Park, West, New York City.

The Metropolitan Life Insurance Company has recently had a list compiled of all institutions in the United States and Canada having for their object either the prevention or treatment of tuberculosis. It has also issued a pamphlet entitled, "A War Upon Consumption," to be distributed among the policy-holders, giving in simple and concise form the fundamental facts concerning tuberculosis. The company requests in this article that if for any reason a policy-holder should think he had tuberculosis, he should fill out the form blank on the last page of the pamphlet and return it. As soon as this blank is received a list of the institutions in his locality will be immediately forwarded.

Fire in a State Hospital.—Three wards of the Vermont State Hospital at Waterbury, Vt., were destroyed by fire on December 24. The loss was in the neighborhood of $100,000. No lives were lost.

Epidemic of Acute Anterior Poliomyelitis in Ontario.—There is an outreak of acute anterior poliomyelitis on a somewhat large scale in a country district of Ontario. An inspector of the Ontario Public Health Board has been dispatched and a report will be issued shortly.

Dr. George Morewood Lefferts of this city has resigned from his position of collaborator in the *Internationales Centralblatt für Laryngologie*, which he has held for the past 25 years. Until the year 1900 he held the position of sole collaborator for America, since which time in association with Dr. Emil Mayer, of this city, the latter being now the only collaborator.

Dr. William J. Robinson, editor of the *Critic and Guide*, the *American Journal of Urology*, and *Therapeutic Medicine*, has purchased the Chicago *Clinic* and has consolidated it with *Therapeutic Medicine*.

"Annals of Surgery" Jubilee.—The *Annals of Surgery* with the December number has completed its fiftieth volume. The event is celebrated by the publication of a jubilee number of nearly 400 pages, containing articles from surgeons of many different countries and an exceptionally profuse set of illustrations.

The Bulletin of the Municipal Commission on Tuberculosis of St. Louis has recently been put in charge of Dr. Kenneth W. Millican as editor. Dr. Millican was formerly associate editor of the *New York Medical Journal*, was on the editorial staff of the *Journal of the American Medical Association*, and editor of the *St. Louis Medical Review*.

Philadelphia Academy of the Natural Sciences.—At the annual meeting held December 22 the following officers were elected for the ensuing year: *President*, Dr. Samuel G. Dixon; *Vice-presidents*, Dr. Arthur E. Brown and Dr. Edwin G. Conklin; *Recording Secretary*, Dr. Edward J. Nolan; *Corresponding Secretary*, Dr. Percy G. Moore; *Treasurer*, George Vaux; *Librarian*, Dr. Edward J. Nolan; *Curators*, Dr. Arthur E. Brown, Dr. Samuel G. Dixon, Dr. Henry A. Pilsbury, and Witmer Stone; *Councillors*, Dr. Philip P. Calvert, Dr. Thomas Biddle, Frederick Prime, Frank J. Keeley.

The Eastern Medical Society of the City of New York, at a meeting held recently, elected the following officers to serve during the year 1910: *President,* Dr. J. Rongy; *Vice-presidents,* Dr. A. Hymanson and Dr. M. M. Stark; *Recording Secretary,* Dr. M. O. Magid; *Corresponding Secretary,* Dr. H. E. Isaacs; *Treasurer,* Dr. J. Bieber.

The East Side Physicians' Association.—The annual meeting of this society took place at Scheffel Hall, December 23, 1909. Dr. Simon Flexner delivered an address on "Medical Education and Medical Publications of 1890." The following officers were elected: *President,* Wm. M. Leszynsky; *First Vice-President,* Max Ghertler; *Second Vice-President,* Sigmund Epstein; *Secretary,* David L. Satenstein; *Treasurer,* Herman C. Frauenthal; *Trustees,* Robert Abrahams, William S. Gottheil, Abram Brothers; *Chairman Committee on Admissions,* Armin Nettle; *Chairman Committee on Ways and Means,* George Dow Scott.

The United States Pharmacopeal Convention will be held in Washington on May 10, 1910, for the first time as a corporate body. The chairman of the committee on credentials and arrangements is D. Oliver T. Osborne, of New Haven, Conn., and the secretary is Dr. Murray Galt Motter, 1841 Summit Place, N. W., Washington, D. C.

The Cass County (Iowa) Medical Society at its meeting, December 9, elected officers for the ensuing year: *President,* Dr. Mynard of Adair; *Vice-President,* Dr. Morris of Atlantic; *Secretary and Treasurer,* Dr. Max Emmert of Atlantic.

The Central Willamette Valley (Ore.) Medical Association, at a meeting, December 3, 1909, elected officers for the coming year as follows: *President,* Dr. Dale of Harrisburg; *Vice-President,* Dr. J. C. Booth of Lebanon; *Secretary,* Dr. Kavanaugh of Albany, and *Treasurer,* Dr. Ellis of Albany. The association is composed of doctors from Linn, Benton and Lincoln counties.

The Cumberland County (Maine) Medical Society held its annual meeting in Portland, December 10, 1909, and elected the following officers: *President,* Dr. Alfred W. King; *Vice-President,* Dr. S. E. Sylvester; *Secretary,* Dr. George Knight; *Treasurer,* Dr. A. S. Gilson; *Censor,* Dr. Willis Bryant Moulton.

The Dallas County (Tex.) Medical Society, at a meeting held December 4, elected the following officers: *President,* Dr. Edward H. Cary; *Vice-President,* Dr. Thomas Benton Fisher; *Secretary,* Dr. Albert W. Nash.

The El Paso County (Colo.) Medical Society has elected the following officers: *President,* Dr. Gerald B. Webb; *Vice-President,* Dr. Z. H. McClanahan; *Secretary,* Dr. L. H. McKinnie, and *Treasurer,* Dr. George G. Gilmore.

The Jackson County (Mo.) Medical Society at a meeting at Kansas City, held December 7, elected officers as follows: *President,* Dr. B. C. Hyde; *Vice-President,* Dr. J. D. Griffith; *Secretary,* Dr. E. L. Stewart; *Treasurer,* Dr. F. Kuhn.

The Johnson County (Iowa) Medical Society has elected officers for the coming year as follows: *President,* Dr. C. L. Van Epps; *Vice-President,* Dr. C. W. Harned; *Secretary and Treasurer,* Dr. L. W. Littig; *Censor,* Dr. F. L. Love.

The Kent County (Mich.) Medical Society at its annual meeting at Grand Rapids, elected the following officers: *President,* Dr. Richard R. Smith; *Vice-President,* Dr. J. D. Brooks; *Secretary,* Dr. J. D. Hastie; *Treasurer,* Dr. A. V. Wenger.

The Kent County (R. I.) Medical Society meeting at Providence, elected officers for the ensuing year as follows: *President,* Dr. John A. Mack; *Vice-President,* Dr. William S. Reoch; *Secretary,* Dr. Thomas F. Darby; *Treasurer,* Dr. Frank D. Smith.

The Lake County (O.) Medical Society met at Painesville December 6, and elected the following officers: *President,* Dr. J. W. Lowe, of Mentor: *Secretary,* Dr. H. L. Spence, of Painesville; *Treasurer,* Dr. C. M. Hawley, of Painesville.

The Lane County (Ore.) Medical Society has reelected the following officers: *President,* Dr. William Kuykendall; *Vice-President,* Dr. A. W. Kime; *Secretary and Treasurer,* Dr. J. F. Titus.

The Morgan County (Ala.) Medical Society at a meeting held on December 2, elected the following officers: *President,* Dr. W. L. Dinsmore of Decatur; *Vice-President,* Dr. F. B. Hunter; *Secretary-Treasurer,* Dr. J. L. Gunter; *Censor,* Dr. W. B. Watson.

The Racine County (Wis.) Medical Society has elected the following officers at a meeting held at Racine, December 9, 1909: *President,* Dr. W. P. Collins; *Vice-President,* Dr. W. A. Fulton, of Burlington; *Secretary and Treasurer,* Dr. Susan Jones of Racine.

The St. Joseph-Buchanan County (Mo.), Medical Society, meeting at St. Joseph, elected the following officers: *President,* Dr. C. R. Woodson; *Vice-Presidents,* Dr. F. H. Ladd and Dr. Levi S. Long; *Secretary,* Dr. Charles W. Fassett; *Treasurer,* Dr. J. M. Bell; *Censor,* Dr. O. B. Campbell.

The Shawnee County (Kan.) Medical Society has elected the following officers: *President,* Dr. C. F. Menninger, of Topeka; *Vice-President,* Dr. M. C. Porter; *Secretary,* Dr. H. M. Connor; *Treasurer,* Dr. S. A. Johnson.

The Sonoma County (Cal.) Medical Society has elected the following officers: *President,* Dr. S. Z. Peoples of Petaluma, *Vice-President,* Dr. J. Walter Seawell of Healdsburg; *Secretary,* Dr. Jackson Temple of Santa Rosa; *Treasurer,* Dr. Lizzie Lane, of Santa Rosa.

The Waukesha County (Wis.) Medical Society, meeting at Wales on December 3, elected the following officers: *President,* Dr. A. J. Hodgson of Waukesha; *Vice-President,* Dr. William T. Murphy of Waukesha; *Secretary and Treasurer,* Dr. R. E. Davies of Waukesha.

Obituary Notes.—Dr. Samuel Benedict St. John of Hartford, Conn., died at his home December 22, 1909, aged 64 years. He was a graduate of the College of Physicians and Surgeons of New York in 1870. Dr. St. John was well known as an ophthalmologist, having practised in New York before going to Hartford. He was a member of the New York Academy of Medicine, the American Ophthalmological Association, the American Otological Association, and the American Medical Association. Dr. St. John was the ophthalmic and aural surgeon to the Hartford Hospital and consulting ophthalmic and aural surgeon to the St. Francis and the Litchfield County Hospitals.

Dr. J. Preston Miller of Washington, D. C., died recently at his home, aged 58 years. He was

a graduate of the Medical College of Ohio in 1877 and was a member of the Medical Association of the District of Columbia and of the American and British Medical Associations.

Dr. Robert Miller of Providence, R. I., died at his home December 17, 1909, after a long illness. Dr. Miller was a graduate of Brown University in 1858 and of the medical department of the University of Pennsylvania in 1861. He was assistant surgeon of the Fourth Rhode Island Regiment during the Civil War. For many years Dr. Miller was a member of the visiting staff of Rhode Island Hospital and was a member of the Providence District Medical Society and the Rhode Island Medical Society.

Dr. William Kelly Newton of Paterson, N. J., died at his home December 19, 1909, aged 59 years. He was a graduate of the College of Physicians and Surgeons of New York in 1877. Dr. Newton was visiting physician to the Paterson General Hospital and president of the New Jersey Sanitary Association and the Passaic County Medical Society. He was also president of the first meeting of the Pure Food Society in Washington.

Dr. Albert H. Blanchard of Sherborn, Mass., died at his home December 5, 1909, aged 81 years. He was a graduate of the Harvard Medical School in 1851 and was a member of the Middlesex County Medical Society and the Massachusetts Medical Society. During the Civil War Dr. Blanchard was surgeon to the Third Massachusetts Cavalry.

Dr. Eugene G. Wood of Oakland, Cal., was shot on December 9, 1909, aged 40 years. He was a graduate of the College of Physicians and Surgeons of San Francisco in 1900 and was a member of the Alameda County Medical Society, the Medical Society of the State of California, and the American Medical Association.

Dr. Oscar K. Richardson of Minneapolis, Minn., died at his home December 10, 1909. He was a graduate of the medical department of the University of Minnesota in 1893.

Dr. Thomas M. Curran of Felton, Pa., died on December 20 at the age of 48 years. He was graduated from the medical department of the University of Pennsylvania in the class of 1882.

Dr. Daniel T. Pope of Edisto Island, S. C., died at his home recently, aged 72 years. He was a graduate of the Medical College of the State of South Carolina in 1860 and served as surgeon in the Confederate Army.

Dr. John Emil Traub of New York City died at his home December 25, 1909, aged 46 years. He was a graduate of the College of Physicians and Surgeons of New York in 1886. He had been retired from practice for several years.

Dr. Henry Martin Weeks, superintendent of the Eastern Pennsylvania Institution for the Feebleminded and Epileptic, died at Spring City on December 17, at the age of 59 years. He was graduated from the New York University Medical School in the class of 1873. He was a member of the New Jersey State Medical Society.

Dr. Benjamin R. Perkins died at Philadelphia on December 22 at the age of 83 years. He was graduated from Jefferson Medical College in the class of 1877.

Dr. John R. Ruffell died of pneumonia at Philadelphia on December 22 at the age of 32 years. He was graduated from the Hahnemann Medical College and from the Medico-Chirurgical College in the class of 1898.

Correspondence.

THE PHYSICIAN AND HIS FEES.

To the Editor of the Medical Record:

Sir:—At a recent meeting of the New York Medico-Surgical Society, Dr. Otto Kiliani read a paper with the above title. The burden of his theme was that the physician is underpaid—that the price of living is high, and that the doctor's income is often less than that of the bricklayer, and sometimes no greater than that of the hod-carrier. That in order to obtain a livelihood some doctors resort to dishonorable means. This is probably a plain statement of the facts, and we may ask, in the language of the immortal Tweed, "What are you going to do about it?" This the doctor does not tell us—he points out the evil and leaves us to seek the remedy. It would seem to the writer that the only way to cure the evil is to remove its cause. The cause is not far to seek—the overcrowding of the medical profession and the abuse of medical charity. It cannot be denied that there are more doctors in this country than there is any necessity for, "and the cry is still they come." Our medical colleges annually vomit forth thousands of medical graduates—good, bad, and indifferent—with utter disregard for the law of supply and demand. What becomes of these graduates after they leave college is no concern of the faculty. The students' fees are necessary to the existence of many of these institutions, and therefore their doors are open to all comers. The talk that we hear about severe "entrance examinations" is only a little pleasantry indulged in by the facetious members of the managing boards of these establishments. Many of their graduates cannot write a sentence in English correctly, and they know no other language. Is it probable that they were educated when they entered the medical college and so fearfully ignorant when they left it? That would not reflect much credit on their Alma Mater. It seems that we have at present in this country 141 medical schools (notwithstanding that several of them have perished from inanition recently), probably more than in the United Kingdom, France, Germany, Italy, and Russia put together.

The baneful effects of overcrowding in the medical profession are become manifest. Active competition develops the commercial spirit in medical men and makes them willing to sacrifice professional dignity and self-respect in order to increase their income. If physicians were all equally intelligent and honorable, the danger to the profession from overcrowding would not be so great as it is at present. Young men are allowed to begin the study of medicine with an entirely inadequate preliminary mental training. No man should be allowed to enter a medical college who has not a good general knowledge of English and some knowledge of Greek and Latin. He should be able to speak, read, and write French or German fluently. Some practical knowledge of natural philosophy is exceedingly desirable. During the first four years of his medical curriculum the student should be compelled to devote all his time to the study of anatomy, histology, chemistry, physiology, and pathology. A knowledge of anatomy, normal and pathological, constitutes the very foundation of a medical education. An old French physician said to the writer when about to begin the study of medicine: "Faite de l'anatomie, et encore de l'anatomie—un anatomiste est un médecin." With these views the writer is entirely in accord. The perfunctory, slipshod way in which anatomy is taught in most of our medical schools is disgraceful in view of the great importance of the subject. Not 5 per cent. of our medical graduates know anatomy as they should know it in order to be safe practitioners. If left to himself, the average student soon tires of the preliminary branches. He wants to attend clinics and witness operations. He wants to get what he considers practical knowledge; in other words, to put on the cupola before he has laid the foundation stone. In this he is encouraged by the method of teaching in vogue in our schools. He is allowed to pummel a chest and maul an abdomen with no accurate knowledge of the structure, topography, and functions of the viscera contained in those cavities. He witnesses operations without knowing the surgical anatomy of the parts involved, and the only result of his attendance at these surgical clinics is a waste of valuable time. The writer would advocate a four years' course devoted

entirely to the fundamental and scientific branches. Having passed a satisfactory examination, the student should receive the degree of M.D. This, however, should not entitle him to practise; he should be compelled to devote one year to post-graduate work in a post-graduate school having a large hospital attached. In such an institution all the practical branches should be taught by competent men. This would afford an opportunity for actual clinical study, that is, study at the bedside, not from the last row of benches in the ampitheater of a hospital with the patient at such a distance as to require the use of an opera glass. As a large number of cases would be congregated in the same hospital, the student would save much of the time which is now wasted in going from hospital to hospital. This would necessitate a change in some of our post-graduate schools. They would be recognized as legitimate and most important seats of learning, and would be forced to modify their methods of teaching so as to adapt them to the requirements of men thoroughly trained in the preliminary scientific branches, and therefore quick to discern incompetence in their teachers, instead of being, what they now are, places to which the verdant practitioner from the rural districts comes with the idea of putting himself *au courant* of everything relating to advanced medical science in the space of six weeks. Post-graduate schools should be devoted to clinical teaching only. At the end of the year, if the post-graduate has been diligent and faithful in his clinical work and passes a satisfactory examination, he should receive a certificate entitling him to present himself for examination for license to practise. Licenses should be granted by a national examining board to all candidates who have fulfilled the requirements and passed a satisfactory examination on the final branches only. The license issued by the national examining board should entitle its owner to practise medicine anywhere within the territory of the United States. Four years devoted to the study of the fundamental branches would prepare the student to undertake intelligently the study of disease in the living body. This system of medical education would effect a great reform. Every graduate of a medical school would be a doctor in the true sense of the word. Our present system of teaching is radically wrong. Didactic lectures, so-called, should be abolished. Any intelligent student can learn more by carefully reading a good book than by listening to a tiresome lecture in a close, vitiated atmosphere. Moreover, he could select his author; unfortunately, he cannot select his teacher—the faculty does that for him, and he must swallow his dose *nolens volens*. If men were chosen as lecturers on account of their special fitness to teach the subject assigned to them, the case would be different; didactic lecturing might then claim certain advantages. But it often happens that a man is appointed to teach a subject that he does not understand, and that he could not teach even if he did understand. Teaching is an art which but few possess. This fact is overlooked by the faculty and trustees of our medical colleges. Very often it happens that the only claim of the appointee to preach medical doctrine is his unfitness to practise. The poor, unfortunate student listens patiently to this would-be teacher until study becomes "a weariness of the flesh."

The study of gross and minute anatomy cultivates the kind of memory designated by the French, "la mémoire des yeux," and enables the student at the bedside quickly to create a mental picture of an inflamed lung, liver, or kidney, and of the relation of the parts involved in a surgical operation. A practical knowledge of this subject is the only kind of knowledge that is worth anything, and the sooner our teachers find this out and mend their ways the better. No man can master the preliminary branches in two years, even if he devotes his whole time to them, but when half his time is wasted by the stupid arrangements as regards lecture hours, he is badly handicapped.

The multiplicity of medical colleges of all grades in the United States undoubtedly tends to lower the standing of the medical profession. Large numbers of medical graduates are turned loose on the community every year who are absolutely unfit to practise. If, according to Bacon, "knowledge is power," ignorance is also power; and the influence exerted on the profession and the public by ignorant medical men is a power for evil which is much to be deprecated. If, in the language of Shakespeare,

"Ignorance is the curse of God,
Knowledge, the wing wherewith we fly to heaven,"

let us try to increase the knowledge of the medical profession by improving our methods in medical education and prolonging the period of study. Let us raise the standard of medical education in this country until the diploma of any medical college that owes allegiance to the Stars and Stripes shall command the respect of the whole medical world. When we shall have done that we shall have done our whole duty to the profession and to the public; for our medical men will then become educators of the public and will aid in the eradication of ignorance, superstition, and blind faith in drugs, and substitute therefor a substantial knowledge of the laws of health and the conservative force of the *vis medicatrix naturæ*. It is true that the adoption of the plan herein suggested might prove the death knell of some of our medical schools, but this would not cause a deluge of tears from the intelligent members of the profession. Many of these schools have no *raison d'être*, except the love of self-aggrandizement which springs eternal in the breast of certain disciples of Esculapius and causes an undying yearning to be known as "professors." These professors, like Othello, would find their occupation gone, but the general improvement in the ranks of the profession would more than offset the feeling of woe experienced by the surviving members of the defunct faculty.

As regards the abatement of the abuse of medical charity, the writer has no suggestion to offer. That the abuse of medical charity exists to a shameful extent there can be no question. That it tends to pauperize and degrade a large proportion of the population, and to rob the struggling young doctor of his legitimate income, there can be no doubt. The advent of a Moses to lead us out of the wilderness is "a consummation most devoutly to be wished for."

G. H. Balleray, M.D.

Paterson, N. J.

OUR LONDON LETTER.

(From Our Regular Correspondent.)

INFUNDIBULAR EXTRACT—RÔLE OF FATS IN GASTRIC DISORDERS—STRANGULATED INTESTINE IN A CHILD—ANOTHER TUBERCULOSIS EXHIBITION—HOSPITAL FUNDS—COLLEGE OF SURGEONS—OBITUARY.

London, December 10, 1909.

Infundibular extract has recently been placed on the market in a form convenient for use. We may consequently expect it will be tried by therapeutists in the direction pointed out by Dr. Blair Bell, whose researches on the pituitary body have added considerably to our knowledge and who last month read a paper before the Liverpool Medical Institution in which he indicated the clinical results he had obtained in the Royal Infirmary. Oliver and Schäfer found that an extract from the pituitary body raised the blood pressure, but to a less degree than adrenal extract. Howell found that it was only the infundibular portion which produced the effect. In the form of powder it has been at times given as a diuretic by a few prescribers. Dr. Blair Bell took up the investigation of it some three years ago and he has now little doubt that it will have a permanent place in therapeutics. He says it not only raises the blood pressure, but keeps it up for several hours and is therefore of special value in shock in which the effect of adrenalin is too evanescent to be of use. It should be followed at once by saline infusions which it cannot supersede. A further and even more important effect of the extract is to cause powerful contractions of the uterus. Having found that it had a special action on the uterine muscle of the rabbit, he proceeded to apply this knowledge to therapeutical investigation and found that the contractions produced in the pregnant, puerperal, and menstruating human uterus are more powerful and more prolonged than those caused by any other preparation, not excluding the most active preparations of ergot. In serious cases this is most important. In two of cesarean section the naked eye effect of a single injection was immediate—the uterus becoming a "blanched ball," and only relaxing subsequently to a moderate extent. The importance of this in relation to subinvolution, hemorrhage, etc., is obvious. Dr. Bell thinks it should only rarely be given before delivery, but he has for some time kept it in his obstetric bag. Further, the extract produces strong peristalsis in the intestines, more than once causing expulsion of the feces. In collapse or shock after serious operations, flatus was observed to pass per rectum within twelve hours—" a happy state of affairs rarely occurring." It

is recommended as a reliable remedy in paralytic distension of the bowels. A special effect on the heart and kidney was observed. After a short initial increase of frequency, the heart's pulsation became slower, with more powerful contractions, and that, too, though in less degree, with patients under the influence of atropine. On the kidney the diuretic effect was marked and in this respect opposed to adrenalin. Dr. Bell concludes from his experiments that the chief effect of the extract is peripheral and he expects the active principle will shortly be isolated.

Sir James Barr, while congratulating Dr. Bell on his research, said the drug is likely to produce arteriosclerosis and so should be used cautiously. If given as Dr. Bell advised, only when the pressure was low, it would be of great value.

Dr. Pentland Hick, who had assisted in the experimental work (as was fully acknowledged by Dr. Bell), said the extract would be dangerous in cases of heart failure.

Mr. Paul had had remarkable success with it in post-operative intestinal naresis. So also had Mr. F. Jeans.

Drs. Hope Simpson and Buchanan reported relief in splenic anemia with ascites, given at intervals over several weeks. The fluid was kept down and the spleen diminished in size.

Dr. Glynn thought it of less use in intestinal atony from acute general peritonitis than in that due to other causes.

The rôle of fats in gastric disorders, since the investigations of Pawlow, has excited a good deal of attention among general practitioners and also among a number of their dyspeptic patients, on account of the prescription of that which had been popularly held to be injurious. But the fact that the gastric secretion is hindered by fat naturally led to its use when that secretion seemed to require checking. The subject was brought before the Medical Section of the Royal Society of Medicine by Drs. Craven, Moore, and R. L. Ferguson, who tried the effect of giving olive oil or almond oil and found that either diminished the digestive power of the stomach, both with regard to the degree of acidity and peptic activity. They gave about one ounce of oil before a test breakfast in some sixty cases. The effect was pretty constant, but there were some variations, according to the condition of the digestion in the different cases. The acid regurgitation and tendency to spasm in pyloric or duodenal ulcer seemed to be relieved by the oil and was perhaps opposed to the view that these symptoms were due to regurgitation of the contents of the duodenum.

Dr. Hertz reported that for two years he had been treating ulcer of the stomach and duodenum for a day or two with an exclusively oil diet, which he found quite removed the pain. In cases of hemorrhage it was better than rectal feeding, which is always accompanied by gastric secretion. In no case had he met with intolerance of the diet, which he continued after the few days to such an extent as to give a dose of oil before every meal. Recurrence of symptoms was thus avoided. Dr. Saundby thought the oil relieved hyperacidity. He gave it as emulsion. Dr. R. Hutchison thought less unpleasant treatment sufficient for hyperchlorhydria, and that rest in bed would be enough to relieve the pain of ulcer. The effect of oil on the pancreatic secretion had yet to be investigated. He rather took a chemical view of the matter.

In the Section for Children's Diseases there was a good show of cases on the 26th ult., after which Dr. Lockhart Mammery read an account of a case of strangulation of the small intestine in a child aged fifteen months. An operation for intussusception had been performed when the patient was five months old and on the appearance of acute obstruction again it was assumed that a similar cause was at work. There was a distinct tumor on the right side of the abdomen. An opening was therefore at once made, when a loop of the small intestine was found acutely strangulated by a narrow band. This was divided and the abdomen closed. The operation was done within nine hours of the onset of the symptoms. Recovery was uninterrupted.

Princess Marie Louise of Schleswig-Holstein opened on Wednesday a Tuberculosis Exhibition for Paddington. Lady Aberdeen was to have been present and speak, but the sad motor accident to her son prevented. The Mayor of the borough said the death rate from consumption was not so heavy as in some places, but in the part where the exhibition is placed it is above the average. It is the poorest and the most thickly inhabited district. The Medical Officer of Health said that, serious as things now are in London, there has been improvement throughout the country in the period from 1851 to 1907. It was now held that the disease was preventable and even curable. The public needs educating on this matter, and these exhibitions are for that purpose.

This one will be open free daily from noon to 9:30 P.M. until the 16th inst., and every day there will be popular lectures and demonstrations with lantern slides by well-known medical men, and ladies and gentlemen will be present to explain to visitors the exhibits.

At a meeting last week of the Hospital Sunday Fund, the Lord Mayor presiding, it was announced that the year's collection (the thirty-seventh) amounted to £72,650. The working expenses for the year were £900 less than in 1908. The report was adopted on the motion of the Lord Mayor, who congratulated the Council on the vigorous and healthy condition of the fund.

The Saturday Fund up to the present, I learn, amounts to £19,734, which is an increase of £50 on last year, although the books for 1908 were kept open a week longer than usual. This year's amounts will close on January 10, so there is a prospect of something more coming in as the honorary collectors forward what they may have in hand.

Yesterday the College of Surgeons admitted a number of new Fellows and Dental Licentiates and adopted the recommendations of the joint committee of the two colleges to recognize the schools of medicine for women in London and Edinburgh, the Royal Free Hospital of London, and the health laboratories of the Edinburgh colleges.

Recommendations of the museum committee relating to the admission of female medical students to the Hunterian Museum were also approved.

Mr. Charles R. B. Keetley, F.R.C.S., senior surgeon to the West London Hospital, died quite suddenly on Saturday, the 4th inst., aged sixty-one. Mr. Keetley was a Bart's student and became a demonstrator of anatomy there, having qualified at the two colleges in 1873. In 1876 he took the surgical Fellowship and soon after found his place on the West London staff, on which he steadily worked for above thirty years. He contributed freely to the societies and journals. You will no doubt remember his "Index of Surgery," a favorite with the younger men, now in its fourth edition.

Department Inspector-General Frederick William Blake, M.D., died on the 4th inst. at the age of eighty-five.

Another Department Inspector-General has passed away in Thomas Seccombe, M.D., in his ninety-first year. He was an Edinburgh student and graduate, entered the naval medical service in 1845, and retired in 1880 with the Burmese medal and other honors.

Lieutenant-Colonel C. E. W. Bensley, late of the I. M. S., and formerly H.E.I.C.S., died on the 5th inst. at Kensington in his seventy-sixth year. He was M.D., St. Andrews, and M.R.C.S. and had a long and varied career in India; he served in the Mutiny campaign, 1857-1858, for which he had the medal.

Another Mutiny veteran passes away in Dr. Alex. Groves Duff, whose death is reported from New Zealand, where he had lived many years and was at one time surgeon to the Totura Hospital. He was born at Calcutta in 1834.

Progress of Medical Science.

Journal of the American Medical Association, December 18, 1909.

The Optic Thalamus.—C. L. Dana recognizes three groups of symptoms from thalamic lesion: one consisting of such symptoms as disturbance of the intelligence due to the general effects of an injury to the brain; second, pressure symptoms on the adjoining parts or their partial involvement in the lesion; and third, the disturbances due to the injury of the thalamus itself. The general symptoms vary according to the individual, and have little bearing on the question of localization. The most important of the second class, the pressure symptoms, were those causing the hemiplegia, and were due to the thalamic clot pressing on or tearing the internal capsule and the quadrigemina and midbrain. These, in his cases, consisted only in pupillary inequalities and paralyses of reflexes. Disturbances of ocular movements and forced movements of the body, and choreic and athetoid movements, which have been seen in

other cases and might have been expected, were not observed by him in his cases. The same is true of hemianopsia, which occurs when there is involvement of the primary visual centers, including the lateral geniculate body and posterior quadrigemina or their connecting tracts. The most definite symptoms connected with injury to the thalamus itself seem to be central pain, some anesthesia, and perhaps some hemianopsia. The two latter may be due to a lesion which is extrathalamic. Whether vasomotor and temperature changes occur or the visceral centers can be affected, is yet to be proved, but the more recent cases observed by Dana seem to indicate that extensive lesions in the thalamic zone at least do cause such results. The pain involved the paralyzed side only; it involves the arms and hands most, the leg and foot next, rarely the head; it is most severe in the most peripheral parts, *i.e.* the hands and feet, and it may be very distressing. It is different from ordinary pain as a rule, being a sort of burning discomfort more distressing than sharp or aching pain. Even when it is only slight it seems to annoy the patient intensely. Sometimes it is said to be neuralgic or shooting, but he has not observed such. In all his patients with autopsies, there were pupillary changes. They were usually unequal, and one or the other was rigid. In none of his cases did he observe the so-called paralysis of the emotional expression or any decided explosive laughter or crying unless there were symptoms indicating lesions of other parts than the thalamus. The hemiplegia, if persistent, as it usually was, was not accompanied by any increase in the reflexes or signs of involvement of the motor tract. The lack of choreic or athetoid movements has been noted, and he thinks, whatever their cause, they are more likely to happen in children than in adults. He thinks his studies confirm, in a general way, the views of Roussy, whose elaborate memoir is praised by Dana, especially for its clinical and pathological work. Both he and Roussy apparently have come to the conclusion that the old idea that the thalamus controlled the movements of the emotional expression, is incorrect, but he still believes that thalamus lesions extending into other tracts do produce these results. The tendency of the investigation of Sachs as well as those of Roussy, and the comparative anatomical studies of Edinger, is to show that the thalamus is essentially only an organ for the reception and distribution to the cortex of sensory impressions, and that it has the function assigned to it by Meynert thirty years ago, when he said that it was an organ which received sensations and registered them in consciousness. There is still some dispute as to whether it has efferent tracts to the cranial and spinal motor nerve, acting as a reflex center of a high order. It does, however, send efferent fibers to the longitudinal bundle. There is also some question as to whether there are fibers from the cortex to the thalamus, and the question whether the thalamus has centers for vasomotor and thermic regulation or for the visual organs is still unsettled. We know enough, he says, however, to recognize thalamic lesions, and may know still better from future investigations. The syndrome varies a little according to the location of the lesion, as it has vascular supply from several sources and cannot be easily destroyed altogether by one vascular lesion.

Levulosuria in Hepatic Cirrhosis.—E. H. Goodman reviews the literature of the levulosuria test in hepatic cirrhosis and gives details of his own experiments made by giving 100 grams of levulose dissolved in 500 c.c. of tea or water given on a fasting stomach after the morning evacuation of the bladder. The urine was collected each hour, for four successive hours, in four separate bottles, after which breakfast was taken. Each specimen, including that that passed before the beginning of the test, was examined separately by the Fehling, Nylander, Seliwanoff, and fermentation tests, and the combined urine after the administration of the levulose by the above tests and, in addition, by Rosin's method and by the polariscope. As the number of cases increased the spectroscopic examination was omitted. The results are tabulated in the case of 32 patients suffering from cirrhosis or congestion of the liver in all but two or three cases. He sums up his results as follows: "(1) Alimentary levulosuria is almost a constant phenomenon in cirrhosis of the liver. (2) The early or late appearance of levulose may be regarded as a sign of severe or mild hepatic disease. (3) Alimentary levulosuria is a useful aid in diagnosing between cirrhosis on the one hand and chronic passive congestion on the other. (4) A study of the hepatic function with glucose and with saccharose in addition to levulose is to be desired, inasmuch as there may be an individual intolerance to carbohydrates. (5) While not indicative of any specific organic lesion of the liver, alimentary levulosuria is most frequently observed in cirrhosis."

Localized Subphrenic Tuberculosis.—C. A. Powers reports the case of a young man with arrested pulmonary tuberculosis who suffered from subphrenic symptoms diagnosed as from gallstones, for which operation was performed. Instead of gallstones, however, a caseous mass about as big as the bowl of a dessert spoon was found between the middle of the upper surface of the liver and the diaphragm and involving both. It was excised with difficulty, together with some outlying tuberculous nodules, and its bed scraped and disinfected with carbolic acid and alcohol. The patient made a smooth convalescence, but some months afterward had a tuberculous appendix removed. Now two years after the first operation the patient is apparently well, with no abdominal or thoracic signs of disease. Powers has not found an exactly similar case in the literature at his command.

Tuberculous Pleurisy.—E. G. Beck discusses the diagnosis and surgical treatment of tuberculous pleurisy. He quotes Widal's rules for the differentiation by cytodiagnosis and says that the inoculation method is not altogether reliable and not very practicable and the tuberculin test is still under question as to its true value. The radiographic test has not been fully appreciated, and he mentions the stereoradiograph as specially valuable. The clinical history, the physical findings, the chemical and bacteriological examination of the blood and secretions, the cytodiagnosis, inoscopy, the tuberculin and inoculation tests, and the stereoradiograph are all aids in determining the character of pleuritic cases. In the treatment there are some inconsistencies. The idea of immediate removal of pleuritic effusion being necessary is still too prevalent among practitioners. There is, however, a growing opinion that the pleural effusion in incipient cases is a factor promoting the cure of the disease by collapse of the diseased lung. Whether the disappearance of the pleuritic effusion under autoserotherapy is of permanent value is questioned by Beck, who thinks that the pleuritic effusion in itself should not be considered a disease and treated as such. It is only a symptom and one of a process that conduces toward healing. The compression of the lung in the treatment of unilateral tuberculosis, as inaugurated by Forlanini and independently practised by Murphy and others, is noticed at length, and Beck is satisfied that this principle of immobilization is correct. He looks at it as one of the most promising fields in the treatment. He gives his own experience in the treatment of empyema with bismuth-vaseline injections and discusses the cause of its healing action. Bismuth vaseline paste (one part bismuth and two parts vaseline), coming in contact with the walls containing the tubercle bacilli induces chemotaxis, and the leucocytes thus drawn to the injected regions destroy the microorganisms present. Their chemical chemical action is slight, and distention of the cavities with the paste and pressure can exercise only a subordinate part in the cure. The exposure of the injected parts to the *x*-ray can likewise be only a secondary factor. He describes his technic. After a radiograph of the cavity has been taken and the secretion examined, he injects 100 grams of bismuth paste and applies gauze dressings daily until the sinus closes. Repetition of the injection is not needed unless the bismuth paste is discharged with the pus and the secretions still show microorganisms. If the temperature remains normal and no unpleasant symptoms arise, the 100 grams of paste injected may be left in for absorption, but if the temperature rises above 101° F., or the patient complains of severe pressure, the accumulated fluid should be drained off and the opening again allowed to close. If bismuth intoxication symptoms appear, the bismuth must be at once dissolved by warm olive oil and withdrawn by suction pump. These tuberculous empyemas are usually preceded by the serofibrinous pleurisy, which, either by tapping or spontaneously, has become infected, and the treatment is usually tedious and unsatisfactory as compared with this method of inducing leucocytosis by bismuth-vaseline injections, according to his experience with these thirteen cases.

Fractures of the Extremities.—E. Denegre Martin says that, while our technic is nearly perfect, we are nevertheless treating more deformed and ununited fractures as secondary conditions than any others in surgery. The reasons for this are given by him as follows: First, the subject is too hurriedly gone over in medical schools, and students have to learn it from the benches. Unless the student secures an interneship in some hospital, his ideas of the treatment of fractures are vague and his experience *nil*. Second not all physicians possess the mechanical skill required. No inexperienced physician would attempt to do a laparotomy for some abdominal condition with which he was not familiar, yet Martin asks how many physicians

would think of referring a simple fracture to a surgeon. It is time, he says, for every practitioner to realize that unless he has had some surgical experience and is equipped with an *x*-ray outfit, it is his duty when possible to refer these patients to properly qualified surgeons. He is glad to see so many medical men now advocating the operative treatment, and sees no reasons why we should not expose a fracture whenever we cannot get good apposition. He suggests that we lay more stress on this branch of surgery, which furnishes more material for malpractice suits than any other.

British Medical Journal, December 4, 1909.

Kala-Azar in the Far East.—P. W. Bassett-Smith says that during the past few years our knowledge of the relationship of the peculiar organisms known as the Leishman-Donovan bodies to many undifferentiated fevers has largely increased. It was long supposed that the chief endemic center of kala-azar was the northeastern part of India, but a disease has been found in North Africa characterized by prolonged fever, enormous enlargement of the spleen and liver, analogous blood changes and a high mortality, in which these same organisms are found. The author gives the history of one case seen in England on his return from the East. The spleen filled nearly one-half of the abdomen, red cells were reduced to 3,000,000 per cm., white cells to 2,000, with a relative increase in the large mononuclear cells. Under treatment with atoxyl the patient greatly improved. Later he returned to the East, where he died. Films are made in this disease by drawing off blood from the liver and the characteristic Leishmann-Donovan bodies are easily demonstrated.

Efflorescence of Urea in Uremia.—J. Cameron refers to the case of a young man in the terminal stage of what was apparently small white kidney without previous symptoms. The patient died or uremia, profuse diaphoreses occurring, partly as a result of spasms and partly as a result of the therapeutic means used. After death relatives called attention to a profuse powdery scurf all over the body, which was explained to them as probably due to urea left by the perspiration after evaporation. Under the microscope the powder showed minute crystals scattered in the deposit, probably those of NaCl. After solution in alcohol, filtration, and evaporation on a glass slide, crystals of urea formed a copious deposit and gave several of the ordinary microchemical reactions. It was noticeable that though free elimination of the urea had been secured the fatal result was not obviated, and this is in accord with previous experience.

The Pituitary Body and the Therapeutic Value of Infundibular Extract in Shock, Uterine Atony, and Intestinal Paresis.—W. H. Bell details his experimentation along this line. He speaks of the anatomy and development of the pituitary body, especially of its posterior lobe, the infundibular. His own work was conducted by injecting an extract of it into animals and by observing the effect of the removal of it in part or wholly. He finds that it raises the blood pressure, and that better when the animal is in a condition of shock than in a normal state. Moreover, it keeps the pressure raised for several hours, whereas the effect of adrenalin in this respect is but temporary. It will not take the place of salines, for on the latter rests the responsibility of maintaining the improvement produced by any remedy. The extract also causes powerful contractions in the pregnant, puerperal, and menstruating uterus. It probably acts better on an atonic organ than on a normal one. The remedy can be employed in a normal labor. Subinvolution due to the defective contraction and retraction is one of the dangers in Cesarean section, especially if performed before the onset of labor; in such circumstances secretions and blood clots may be retained and become infected—a state of affairs favored by any contraction of the pelvis which may be present, for this condition leads to a sagging forward of a subinvoluted organ. The remedy ought to be given, but rarely before delivery. For general post-partum purposes it is better than ergot. It also excites active peristalsis in the bowel. There is little doubt that its chief effect is peripheral, for if we place a rabbit's isolated and active uterus in Ringer's solution the organ contracts violently on the addition of a small quantity of the extract. The remedy is sold in "vaperole" flasks, each of which contains 1 c.c., which is the ordinary adult dose. Solutions are not spoiled by boiling. The dose may be repeated in one hour. After a few doses a short refractory period is established.

Some Uses of Opium.—Eustace Smith discusses the therapy of opium from the older standpoint, before so many sedative remedies were at the disposal of the physician, and he thinks that we have gone astray in forgetting much old knowledge. For relief of pain it is still to be used, for small doses are stimulating as well as sedative. This stimulating action is well seen in cases of indolent ulcers of the skin and mucosa, and can be turned to account in obstinate sores in cachectic children. The circulation is also stimulated and the resistance of the body to depressing influences is notably increased. To old people mentally depressed, nervous people in presence of some depressing event, children wearing drainage tubes, etc., it is especially grateful. Too large doses should, of course, be avoided, and care should always be taken to fit the dose to the susceptibility of the patient. In old persons with bronchial catarrh and profuse expectoration it is contraindicated if the skin is livid, lips blue, and chest oppressed, but it can be profitably and safely used if the breathing be easy, skin clear, and cough quite loose. In inflammation of the serous membranes it must be freely given. It may be given to infants. For a child of twelve months 1/40 gr. morphine may be injected, combined with 1/100 gr. atrophine in cases of spasm, and in half an hour the dose may be repeated if the spasm is not relaxed. When the air passages are alone affected it is better to use grindelia. Opium is of great value in all forms of loose bowels, useful in cystitis combined with painful spasm at the neck of the bladder. As a hypnotic it is free from the depressing effect of many of its modern substitutes, etc. In eight days the drug will have passed out of the system, and if it is found in the urine (during that period) of habitues who are under treatment, it is safe to assume that they are continuing the drug secretly.

Münchener medizinische Wochenschrift, November 23 and 30, 1909.

Bodily Pains of Intestinal Origin.—Ebstein discusses at length the pains and aches of various portions of the body which may be caused by chronic constipation. Not an uncommon location for these toxic neuritides is the region of the nervus trigeminus. Not only is there neuralgia, but there may be point tenderness, especially in the supra- and infraorbital notches. The occipital nerve may also be affected, and constipation is a not uncommon cause of occipital neuralgia. The brachial plexus and its branches may be involved and cause point tenderness in various spots, especially over the radial nerve in the lower third of the upper arm, in the sulcus bicipitalis internus, and between the internal condyle and the olecranon. These are usually accompanied by points in the supraclavicular notch and the neck. Outspoken neuralgias of the brachial plexus arising from constipation have not been seen. Local ostealgias of the thorax, especially over the xiphoid and false ribs, may be caused by the same thing. In the lower extremities the usual seat of the painful points are below Poupart's ligament, to the inner side of the knee, and on the internal malcolus. Knee-joint neuralgias are especially common, and hip-joint affections are not unknown. In such cases the tendon reflexes are often much increased. All of these conditions, even when so severe as to cripple the patient, clear up rapidly as soon as the points are kept well open for a few days.

Intravenous Injections of Suprarenal Extract in Cardiac and Vascular Collapse.—John says that intravenous suprarenal injections are indicated in severe cases of cardiac and vascular collapse which do not respond to the usual cardiac stimulants. The effective dose varies from 0.2 to 1.0 c.c. of the simple suprarenal solution. The use of the same dose in dilutions of 1:10 is of no advantage. After intravenous suprarenal injections the use of other stimulants is superfluous. The danger of death from suprarenal poisoning is present only in the most severe cases of cardiac weakness in the presence of contracted kidneys.

Advance in the Use of Atmospheric Pressure Differences in Thoracic Surgery.—Willy Meyer describes the new high and low pressure chambers which he has had constructed at the Rockefeller Institute and German Hospital for experimental and practical thoracic surgery. His apparatus consists of two chambers, one for the operator and one for the anesthetist, so arranged that either or both may be made positive, negative, or normal, and during an operation these conditions may be varied at will without change in position of any of the parties concerned or interruption of the operation. The operating table is in the middle of the chamber, allowing the surgeon two assistants and plenty of room to move around. Unobstructed relations of understanding between the operator and the anesthetist are possible during the operation. There is sufficient room to allow the general anesthetic to be controlled by two assistants. It is so arranged that neither surgeon nor anesthetists is exposed to the anesthetic. The surgeon can see the

patient's head and the anesthetist the operation field. The ventilation is good, the direction of air currents are controlled, and the pressure can be changed quickly. The rubber collar is adjustable to the patient's neck. There is complete understanding between those within and without the chamber. The apparatus is light and portable, so that it can be used in war.

Surgical Treatment of Chronic Jaundice.—Kehr says that the indications for operation for chronic jaundice are absolute or relative. The absolute indications consist of acute or chronic empyema of the gall-bladder, or chronic closure of the bile ducts. The relative indications are chronic colic, interfering with the patients earning a living. Of 125 gallstone operations during the past year, 100 gave absolute indications and 25 relative. The differential diagnosis between stone and tumor is discussed. If the disease begins with colic, it is probably stone; if insidiously, it is probably catarrhal, pancreatic, or tumor. Catarrhal jaundice lasting over four weeks in an elderly person must be looked at with great suspicion. After six weeks, with loss of appetite and weight, operation must be considered. The danger of chronic jaundice lies in the development of biliary cirrhosis, cholangitis, or a cholemic diathesis. The fear of postoperative hemorrhage should not deter a physician from advising operation. With proper technique there is but very little danger of peritonitis.

The Early Stage of Poliomyelitis.—Müller has studied fifty early cases of poliomyelitis. He reports numerous instances of the disease being carried by a third person. In the febrile stage there may be febrile symptoms alone, or combined with digestive or respiratory affections. Tonsillitis and bronchitis were very common initial symptoms. In many cases others in the family had tonsillitis or gastro-enteritis, without paralytic symptoms. There are three cardinal symptoms for the early diagnosis of poliomyelitis, or of the disease without paralytic symptoms. The first is the inclination to perspire. The second is the frequent and pathogomonic hyperesthesia. The children cry out under the most gentle examining or the slightest movements, and they hold the arms and legs perfectly still. There is weakness of the neck. The head falls backward, but is not held rigidly. The third chief initial symptom is leucopenia, a decrease in leucocytes in spite of fever, angina, or bronchitis. Lumbar puncture showed a clear fluid under pressure, without organisms. The portal of entry is the digestive or respiratory tract, often the tonsils.

Deutsche medizinische Wochenschrift, December 2, 1909.

Serumtherapy, Prophylaxis, and Vaccination for Foot and Mouth Disease.—F. Loeffler says that the foot and mouth disease belongs to the immunity producing diseases. The persistence of the immunity varies, depending upon the intensity of the attack and the virulence of the virus. Definite antibodies are found in the blood of recovered animals. It is possible to increase the amount of antibody by inoculation of a highly virulent lymph. It is possible to prevent the mortality among animals by inoculation of a highly immunized serum. The course of the disease among cattle may be shortened and the after-results decreased by serum treatment. The greatest value of the cattle serum lies in its prophylactic use. Active immunity may be obtained by inoculation of attenuated lymph or a mixture of lymph and serum. The active immunity appears only after five weeks, and is therefore not of great value. The passive immunization by serum is without danger. It appears immediately, but lasts only about two weeks. Repeated injections every ten days of relatively small amounts of serum produces a lasting immunity. The serum prophylaxis has shown its value in numerous epidemics. The serum protects against infection with relatively small quantities of the virus. Contagion from farm to farm occurs by the transference of small quantities of the fresh lymph by carriers, either men or animals. The farm workers are usually ignorant of the danger of carrying the disease, and education in the subject of disinfectives is needed. Prophylactic serum injections are indicated in every infected farm. Systematic inspection is demanded. One of the most important things in the overcoming of foot and mouth disease is the recognition of chronic "carriers." The number of these is small. How long these animals continue to be dangerous is not known. They have been proved infectious seven months after the disappearance of the disease. Convalescent animals must for at least seven months be isolated and treated as dangerous. If this is not possible, the well animals must be given prophylactic doses of serum. The Prussian Ministry of Agriculture has instituted a station for the production of foot and mouth serum, and it is to be hoped that other similar stations will soon be formed.

Therapeutic Value of Hyperemia in Erysipelas.—Jochmann and Schöne conclude a clinical study of the value of Bier's passive hyperemia by saying that in the majority of the cases rapid recovery, characterized by sudden fall of temperature and improvement of the general symptoms, follows the use of this form of treatment. One-fourth of the cases, however, showed no improvement. The author explains this failure to act in all cases by the assumption that in the mild cases and those of medium severity the venous hyperemia increases the resistance of the affected portion of the body against the streptococcus infection, and tends to aid in recovery, whereas in very severe cases this does not occur.

The Identification of Tubercle Bacilli in the Sputum by the Double Method of Ellermann-Erlandsen.—H. Kögel describes this method, as follows: (1) One volume of sputum (10-15 c.c.) is mixed in a stoppered glass with one-half its volume of 0.6 per cent. sodium carbonate solution. The mixture stands twenty-four hours in the thermostat at 37° C. (2) The greater part of the supernatant fluid is decanted and the remainder is centrifugated in a graduated centrifuge tube. The fluid is poured off. (3) Four volumes of 0.25 per cent. sodium hydroxide are added to the one volume of the precipitate. After very careful agitating this is raised to a boil. (4) Centrifugate. The result of this is that practically the entire bacillary content of the whole amount of sputum is spread on one or two slides and 20 to 30 times the number of tubercle bacilli occur per field. The method takes time. In an old sputum the autodigestion may have gone far enough to make the first stage of the procedure unnecessary. Very thick sputa may require 48 hours in the thermostat. Very purulent sputa give poorer results than slimy ones. These must be left longer in the incubator and must be boiled longer, with larger amounts of the caustic. A powerful centrifuge is required, and the centrifugation must be continued long enough to precipitate completely all the solid matter. The final precipitate consists almost entirely of bacteria. A rapid glance is often all that is required for a diagnosis. Specimens which in the usual smear showed 10 tubercle bacilli to the field by the double method showed 300 to 400. As a rule, 15 to 30 times as many were seen. Of 105 specimens of sputum examined, by the usual method 21 were positive. Of those negative, 8 by the double method gave positive results, or an increase of 28 per cent.

French and Italian Journals.

Use of Sterilized Linen in Nurslings.—Edmond Weill has demonstrated that sterilized linen used for dressing infants is a preventive, as well as a curative measure, in the skin suppurations of infants. In an old hospital connected with the University of Lyons there were many cases of pemphigus and pyodermatitis, the buildings being permanently infected by long use with pus microorganisms. Almost all of the children who came there suffered from these skin affections. The author now has all the linen sterilized in bags, in which it is kept until it is to be used for dressing the children. The clothing that has been only washed shows by cultures plenty of colonies of streptococcus and staphylococcus, while the sterilized clothing gives none at all. He recommends the sterilization of all clothing to be used in infants' hospitals. Even when a child has become infected, he says, the use of sterilized linen will promptly cure him.—*Lyon Médical,* September, 1909.

Splenomegaly.—Menotti Bucco finds that the spleen hypertrophies in many neoplastic and inflammatory states. The functions of the spleen are lymphoid. In intrauterine life it is an important hematopoietic organ, but in the adult, when the medulla of the bones is fully developed, this function is lost. Splenomegaly is frequent in many forms of anemia, especially of the chlorotic type. It has been demonstrated that from the spleen originate toxic and infective processes which by way of the splenic vein reach the liver and cause cirrhosis. The toxic and infective principles may also originate in the intestines. The splenic origin of hepatic cirrhosis is common to all cirrhoses, especially malarial cirrhosis. Bucco is of the opinion that one is not justified in affirming the nosological entity of Banti's disease. We can say definitely that the splenic tumor in cirrhosis is in part antecedent and in part consecutive to hepatic cirrhosis. It is possible experimentally to reproduce in animals conditions similar to those in the spleen and liver of Banti's disease.—*Giornale Internazionale delle Scienze Mediche,* September 15, 1909.

Book Reviews.

PYE'S SURGICAL HANDICRAFT. A Manual of Surgical Manipulations, Minor Surgery, and other matters connected with the work of House Surgeons and Surgical Dressers. Fifth Edition, Revised and largely Rewritten by W. H. CLAYTON-GREENE, B.A., M.B. (Cantab.), F.R.C.S. (Eng.), Surgeon in Charge of Out-Patients, St. Mary's Hospital; Lecturer on Anatomy in the Medical School. With 343 illustrations and plates newly drawn for this edition. New York: E. B. Treat & Co., 1909.

THE first edition of this work appeared twenty-five years ago, and during the whole of that period it has enjoyed an established place as a most useful book for internes and medical students. This new edition is thoroughly revised and brought up to date; at the same time it is increased in size by about only fifty pages. The work remains true to its original plan of showing that surgical excellence can be attained only by the acquisition of manual skill or handicraft. For the medical student about to enter the surgical wards there can be no better companion than this book.

DIE CHIRURGISCHEN KRANKHEITEN DER BRUST UND IHRE BEHANDLUNG. Von Dr. CARL BECK, Professor der Chirurgie an der New York Postgraduate Medical School (University of the State of New York); Chef-chirurg des St. Mark's Hospitals, Mitglied des Offizierkorps der Bundesarmee, Präsident der deutschen medizinischen Gesellschaft der Stadt New York, usw. Aus dem Englischen übersetzt, von Dr. SCHRÖDER, Düsseldorf. Mit 16 kolorierten und 251 anderen Abbildungen. Berlin: Verlag von August Hirschwald, 1910.

IN his preface the author calls attention to the fact that American surgeons, while deeply interested in the surgery of the abdomen, have more or less neglected that of the chest. To his original work in English many additions have been made in this, the translation, and the book now contains 471 pages of reading matter and many excellent illustrations. The translation has been well done, and the book has distinct value, though the difficulties inherent in a work of this kind, dealing with a large region of the body, are quite apparent, for it attempts to cover diseases that usually fall to other specialists. For example, the picture of a plaster jacket shows a rather crude product. The chapter dealing with pyothorax is one of the best in the book. The author pays his respects to the advocates of half-way measures in this disease, and describes the technique of operation so clearly that the general practitioner could perform it. This is in marked contrast to what is said on the subject of cervical ribs. A writer is expected to explain his subject as best he can, and to state the difficulties of operation where they exist, but to advise his readers that such and such an operation should be turned over to a skilled surgeon always has an unpleasant sound. The fact that among Germans so large a proportion of whom speak or, at least, read English, the book is considered worthy of translation, is of itself a high compliment.

DAS PROBLEM DES LEBENS IN KRITISCHER BEARBEITUNG. Von Prof. Dr. BERTHOLD KERN, Generalarzt. Berlin: August Hirschwald, 1909.

IT is probable that the average physician reads but little philosophy of the abstract sort, and he certainly writes none. Indeed, if we except Master Francois Rabelais, that early prophet of a joyous pragmatic philosophy, and our own Professor James, who has made the "cash value" philosophy peculiarly his own, the number of physicians who have added to the literature of the attempted solution of the final meaning of life is scant indeed. Professor Kern has, however, contributed two volumes to this important subject, one of which we must now consider. The author is careful to state his fundamental position in the preface, namely, that philosophy and science must unite in considering the physical and spiritual substance of life as identical, and also that in all future investigations the two disciplines must work together. This sets aside at one stroke the crude brain secretion materialism of Cabanis and Vogt, on the one hand, and the pure idealism of the Berkley school, on the other. The only certain thing is that the universe is a world of concepts, and science an attempt to comprehend nature refining and classifying such concepts. With final causes we have nothing to do. To understand life, the laws governing the growth and repair of the body must be appreciated in terms of physics. The psychic mechanism must be studied in the same fashion, for it is a part of the body. No sharp distinction can be drawn between the two; substance and concept are identical. Evolution in all its phases is important as furnishing a guide to the laws of psychic as well as somatic development. Each individual, though bound by laws governing the race, has the intellectual right to set up for himself a philosophy of life, and even a personal religion, if such ideas are not contrary to scientific concepts. In this our author is a pragmatist. Finally, the problem of life is in the last analysis nothing more than the knowledge which we can obtain of nature by the use of criticism and investigation, from both a philosophic and a scientific aspect.

VORLESUNGEN ÜBER HERZKRANKHEITEN. Von Dr. H. BOCK. I Heft. Die Erkrankungen des Herzmuskels, Histologie, Pathologische Anatomie, Diagnose, und Therapie. München: Verlag von H. Thoma, 1908.

THIS pamphlet contains the rather elementary lectures on the diseases of heart muscles delivered by the author in a postgraduate course. The only original element in them consists in the description of a complicated stethoscope invented by the author, which enables the observer to measure mechanically the pitch and value of cardiac sounds. The author claims that the information obtained by this means is much more useful and trustworthy than that given by the usual methods of auscultation.

DIE GICHT UND DIE SALZSÄURE-JODKUR. Von San.-Rat. Dr. FALKENSTEIN, Oberstabsarzt I. Kl. a. d. Gr.-Lichterfelde. Berlin: Hirschwald, 1910.

THE old saying that no physician who has not suffered himself from gout is in a position to treat intelligently patients with that disease seems well exemplified in the person of our author, who has suffered from this complaint for thirty-five years, and who has finally, in his opinion, found a certain remedy for the disease. This consists in the use of dilute hydrochloric acid, four glasses of water, each containing six to ten drops of the acid, being taken each day. If this condition be fulfilled, all will be well. The author indignantly rejects the idea that alcohol should be forbidden, and thinks that smoking after meals is beneficial. Such treatment must inevitably be very popular with many of those afflicted with the disease. In the line of food, also, the author is somewhat iconoclastic, considering that tomatoes and red meat are not to be forbidden to the sufferer, who should avoid only substances with high purin content, such as sweetbreads, liver, and kidney. A purely vegetable diet is not to be recommended, for the human race has been omnivorous for many thousands of years, and probably before that time was strictly carnivorous. It is, therefore, necessary to take only a sensible mixed diet, with a goodly allowance of fresh vegetables. The strictly medicinal treatment of acute attacks follows very closely the traditional notions, with the exception that the author considers that alkalies may be distinctly harmful.

TEXT-BOOK OF ANATOMY AND PHYSIOLOGY FOR NURSES. Compiled by DIANA CLIFFORD KIMBER, Graduate of Bellevue Training School; formerly Assistant Superintendent New York City Training School for Nurses, Blackwell's Island, N. Y.; formerly Assistant Superintendent Illinois Training School, Chicago, Ill. Third Edition. Revised by CAROLYN E. GRAY, R. N. Assistant Superintendent, New York City Training School for Nurses. New York: The Macmillan Company, 1909.

THE former edition of this work contained 271 pages of text, with 149 illustrations and three pages of index. The present edition contains 420 pages of text, 212 illustrations and an index of sixteen pages. But it is not only in quantity that the present revision is apparent. Almost every page shows evidences of careful and painstaking effort on the part of the revisor; the new illustrations have been well selected, and are admirably adapted to the text, and each chapter closes with a summary of its contents clearly outlined, and which cannot fail to be of value, both to the tired and hard-worked student and also to the teacher. The book is compiled for nurses, and the work has been done by one who combines in an unusual degree the threefold knowledge of their peculiar educational needs, of the limited time they have for study, and of how to make the subject both interesting and attractive. After a very careful perusal of this work, and being well acquainted with most of the books written for nurses during the last ten years, we have no hesitation in saying that this is easily the standard work on the subject; and, further, it is a model of what such a text-book should be. Unusual skill has been shown, both in the selection of the subject matter and also in the handling of the same, and the book is remarkably well balanced. The paper and press work are in keeping with the general excellence of the book.

NEW YORK ACADEMY OF MEDICINE.

Regular Meeting, Held December 2, 1909.

THE PRESIDENT, DR. JOHN A. WYETH, IN THE CHAIR.

Election of Officers.—The following nominees were elected to office: *Trustee*, Dr. Abraham Jacobi; *Vice-President*, Dr. L. Emmett Holt; *Secretary*, Dr. John H. Huddleston; *Corresponding Secretary*, Dr. Charles Stedman Bull; *Member Committee on Library*, Dr. Louis A. Conner; *Member Committee on Admission*, Dr. John Rogers.

Report of the Library Committee on Need of Increased Facilities.—It having been reported to the Library Committee that on account of lack of room the functions of the library were being seriously interfered with, and that no provision was being made for the growth of the immediate future, both these questions were taken up by the committee for investigation. If, as seemed probable, all the unoccupied space would be exhausted by January, 1912, it was essential to have new accommodations ready by the summer of 1911, that the books might be shifted during the months when the closure of the library would be less serious. To accomplish this, building must be begun by June, 1910, at the latest, and to this end plans should be laid at once. The only satisfactory way to meet the present situation was to build on a new site with a plan which would prove much more economical of space than the present structure, and which would lend itself to future requirements. The disadvantges of tearing down the existing building and rebuilding on the present site were too obvious to need discussion. In view of the facts brought out by the investigation, the Library Committee felt that it could not too strongly urge upon the Academy the necessity for immediate action in this matter. The following were appointed a committee by the president to consider this subject and to report back to the Academy at its next meeting: Members of the Counsel of the Board of Trustees and of the Library Committee, the chairmen of the various sections, and the surviving ex-presidents.

The scientific session was held under the auspices of the Section on Surgery.

The Medical Aspects of Affections of the Colon.—Dr. LEONARD WEBER read this paper. (1) Dysentery was caused either by the Shiga bacillus or by the ameba. The drugs that had been employed were ipecacuanha, sulphate of magnesium, and the subnitrate or subcarbonate of bismuth. In the few cases of rather severe dysentery which were under his care in 1868 and 1878 he relied upon ipecac, and obtained good results. The main objection to this drug was obvious: the patients could not take it without becoming nauseated. It also depressed the nervous system. English army surgeons and others had reported very good results in hundreds of cases of dysentery with magnesium or sodium sulphate. Bismuth in doses from gr. xv to xxx to 1 drachm, given every three hours, followed by suitable doses of castor oil every third or fourth day, had given him very good results in the limited number of cases, acute and subacute, that he had treated during the past twenty-five years. He asked if it was commendable to use nitrate of silver or other antiseptic solutions for irrigating the colon in acute dysentery. He did not think it was, because the tenesmus and intestinal tormina were generally so acute that the introduction even of a soft nozzle and tube was almost impossible to bear and would add torture to the existing distress. Again, nothing was more unlikely than that of the amebæ could be dislodged from the mucous membrane. (2) Diphtheritic inflammation of the ileocolon in the course of acute infectious disease, or as a terminal process in chronic affections, or through metallic poisoning, might spread over large areas of the mucosa, leading to extensive sloughing. Large doses of bismuth, accompanied by hypodermics of camphor oil, or strychnine to overcome the asthenia, might be of service. When mercury had been the exciting cause, iodide of potassium should be employed. (3) Ileocolitis. Many such cases got well by the use of an absolute milk diet and the use of the gray powder, with an occasional dose of castor oil; but there were many cases of this form of intestinal infection that did better after intestinal irrigation with mild astringents or antiseptic solutions. Dr. Weber preferred the non-irritating solutions of argyrol to those of silver nitrate. In cases of ulceration and perforation of the bowel occurring during the course of typhoid fever, the surgeon should be consulted as to the advisability or necessity of doing a laparotomy. With reference to the question of infection or non-infection in mucous colitis, Dr. Weber stated that he sided with those who looked upon it as a form of neurosis. He had seen a number of cases among apparently healthy women, stout as well as thin ones, such as had had the stigmata of hysteria or other neurosis, as well as among those women who had not. Such patients he advised to take ordinary food, a dose of castor oil occasionally, and to cease by all means inspecting their stools, which they were invariably in the habit of doing. Small doses of the bichloride of mercury and arsenic seemed to be of some service in these cases. In the chronic cases of invasion of the ileocolon catarrh with infiltration, or with hypertrophy and atrophy of portions of the mucosa alternately, which did not offer the signs of ulceration, as in all cases of subacute and chronic diarrhea, there should be made a careful examination of the stools for mucus, pus, shreds of mucous membrane, parasites, and particularly organized material indicating new growth. This was of the utmost importance for diagnosis and treatment. In the chronic infectious diseases of the ileocolon which lead to ulceration and subsequent cicatricial contraction, adhesions, stenosis, and perforation, surgical aid would often be called for: a correct diagnosis of such conditions was often a task of great difficulty. Tuberculosis and syphilis were much more frequently the determining factors here than in dysentery. It was still an open question whether those chronic luetic ulcerations of the rectum which advanced gradually as far as the sigmoid, and led to severe cicatricial stricture, were always due to syphilis and not sometimes to gonorrheal infection. The tuberculous ulcers and strictures occurred mainly in the ileum, and were not infrequently multiple; but in the ileocecal portion veritable tuberculous tumors were met with, and might be mistaken for carcinoma. The highest degree of dilatation in the cecum and colon that he had ever observed occurred in cases of stricture in the sigmoid flexure. Frequent alternation of obstipation and diarrhea should always arouse suspicion of intestinal obstruction. The ribbon-shaped stools seemed to him rather an exceptional sign; of much more importance was the presence of mucus, blood, and pus in the stools. Before closing, Dr. Weber reported three cases. One was a case of hepatic abscess in the left lobe, occurring ten years, or longer, after an attack of dysentery; this patient could and ought to have been saved by timely operation, but the case terminated fatally by perforating into the right pleural cavity. Another case showed that the entire colon might remain filled with feces for two years or more and return to its normal condition after operation. The third case reported proved that even a very aged person could get along without a colon for nearly three years and maintain her health and weight.

Affections of the Colon.—Dr. EDWARD MARTIN of Philadelphia read this paper. The large intestine was commonly regarded as an organ the main function of

which was to accumulate the feces until such time as their final extrusion from the body might be a matter of convenience or pleasure. In conditions of health there was apparently little but water absorbed from the fecal mass by the large intestine; but this condition did not obtain when the mucous membrane of this organ was either actively or chronically inflamed, or when through muscular atony or displacement there was colonic stasis. Under such circumstances the function termed by Reichert biosmosis no longer remained protective, and toxines were readily absorbed. In profoundly toxic conditions the large intestine certainly had an eliminative function. There was reason to believe that many of the ulcerative lesions were those of elimination rather than of absorption. In an experimental work upon colitis due to mercuric bichloride poisoning Saxon demonstrated the absence of colonic lesions after bile exclusion, and believed that the intestinal lesions were not caused by the direct excretion of the poison into the intestinal canal, but by its reabsorption after being excreted by the liver and carried to the intestinal cavity by the bile. The bacterial content of the large intestine was much greater than any other part of the intestinal tract. One-third the weight of the dry feces was said to consist of bacterial bodies. The normal mucous secretion of the large intestine was feebly bactericidal in action. Concerning that class of colonic lesions which, though not regarded as appertaining to the surgeon, was sometimes refractory to medical treatment, the present discussion seemed timely. On theoretical grounds the treatment of acute enterocolitis, if rapidly progressing toward a fatal issue, should be treated by jejunostomy and diversion of the biliary secretion, containing as it probably did the bulk of the toxine absorbed. The operation might be supplemented further by an appendicostomy or cecostomy, provided sufficient colonic lavage could not be given. In typhoid fever accompanied by a profound toxemia progressively overwhelming in type, a fecal diversion some three feet above the ileocecal valve would seem indicated, thus lessening toxic absorption, protecting the lesions against the irritating effects of putrescent intestinal contents and allowing of cleansing irrigations. When dysenteric lesions were considered, the theoretical advantages incident to surgical interference were reinforced by clinical experience, and in the main were distinctly encouraging. The clinical evidence in favor of surgical intervention in cases of mucous colitis, an affection of middle-aged, constipated, neurasthenic women, luminously described as a secretory neurosis, and characterized by the passage of gelatinous mucus, intesinal casts, and occasionally sand, was not convincing. The symptoms of intestinal toxemia were not characteristic, and did not differ essentially from those incident to toxemia from other sources. There were certain urinary and fecal findings which were suggestive. Perhaps as characteristic of intestinal toxemia as any one symptom was the relief occasioned by a thorough evacuation of the bowels, and the pronounced exacerbation of symptoms incident to the ingestion of an inefficient laxative. A thorough evacuation often implied not only the administration of a purgative, but copious colonic flushings. The commonest ptosis of the large intestine was that of the transverse colon downward, associated with a gastroptosis. At times the entire colon descended The benefit afforded to patients with nephrocoloptosis by the Weir Mitchell treatment of rest and forced feeding was attributed in the main to the recumbent position, since on the assumption of the ordinary routine of life nutritional disturbances again became manifest, and the colonic drag upon the kidney and duodenum began again. In the prophylaxis of visceroptosis the wearing of an abdominal support on getting up after a wasting disease would seem indicated. These ptosis cases, if taken off their guard in a standing position, exhibited a characteristic conformation, a midline pouch hanging down over the pubis made by the stretching of the muscles below the umbilicus. The support should be upward and backward, and was perhaps most effectively accomplished by a carefully fitted double truss with broad plates. There was a class of cases described by Lane in which the intestinal stasis was due to gut fixation dependent upon bands passing from the parietal peritoneum and producing such functional derangement that the large intestine became a foul, undrained, and undrainable sewer. His treatment consisted in an ileosigmoidostomy either with or without complete removal of the colon, the more radical operation being indicated in cases characterized by pain. He had operated upon many patients, but he gave neither the total number nor information concerning the perseverance and skill with which a previous unavailing hygienic, medical, and mechanical treatment was applied, nor were ultimate results noted. It was probably that many of the patients on whom he operated were women with the operation habit, and that they all promptly perished, since the temptation to report a successful case would be a difficult one for an easily fired enthusiast to resist.

Dr. Robert G. LeConte of Philadelphia said that he approached the subject matter of Dr. Martin's paper with diffidence, as his experience was limited and his ideas too vague to frame into definite rules. At the Pennsylvania Hospital their widest experience was with the acute forms of intestinal intoxication, while the chronic form of intestinal stasis had either been infrequent or rarely recognized. As an example of one form of acute intoxication, a case of chemical poisoning was recently admitted to the hospital which illustrated peculiarly the elimination of poisons by the colon. A young woman drank an aqueous solution of phosphorus match heads. On admission she did not seem sick, but the stomach was thoroughly washed out and an antidote allowed to remain in it. Death occurred suddenly twelve hours later, and at the autopsy the transverse and descending colon and sigmoid contained sufficient phosphorus to make the mucous membrane luminous in the dark, while the stomach and small intestine were apparently free. Did this young woman die as a result of an overdose of phosphorus ingested by the stomach, in which the luminous colon was only an expression of elimination, or, had colonic lavage been instituted, might not death have been averted by removing a source of secondary absorption? It would seem to indicate that in such chemical poisons as phosphorus, mercury, etc., colonic lavage was important for the prevention of secondary absorption, as such poisons were eliminated largely through the colon. In the severe forms of acute autointoxication, so-called cholera nostros, they had recently had two typical examples. Both were in middle-aged Italians. The symptoms were sudden onset of abdominal colic, muscular cramps, vomiting, and purging, the bowel movements at first being mucoid, then bloody, and lastly watery, associated with severe tenesmus. The patients were stuporous and in profound shock, exhibiting pinched facies, sunken eyeballs, cyanosis, cold perspiration, subnormal temperature, and rapid pulse, with a shriveled appearance of the skin, a typical picture of shock with dehydration of the tissues. Immediate stimulation with intravenous normal salt solution tided over the crisis, when the colon was irrigated with the same solution, and large quantities were given subcutaneously, by bowel, and by mouth. Both patients recovered. In the acute cases of intestinal intoxication, whether of chemical poisoning or autointoxication, it would seem that there was small indication for surgical intervention. In the chronic cases it was a much more difficult problem to decide when surgery should be undertaken. Their rule was, first, thoroughly to exhaust all medical measures, including medi-

cated colonic lavage. If after a reasonable time the case did not improve, they turned to surgery. As an expression of the difficulty in deciding on the proper treatment, he reported two cases, in one of which a good deal of surgery was done, and in the other the knife was not used. Both patients were strong and vigorous men, in the prime of manhood. Both were suffering from a long-standing dysentery, nonamebic, with the frequent passage of bloody stools and occasional casts of the bowel. Each was ill about a year and wasted almost to a skeleton, with marked anemia and profound prostration. Ulcerations in the rectum were deep and numerous. In one, his colleague, Dr. Gibbon, did an appendicostomy, and when, later, stricture of the upper portion of the rectum developed, an anastomosis was made between the lower end of the ileum and the rectum, below the stricture. The appendical sinus was closed at a subsequent operation. In the other, medical treatment was persisted in, with colonic lavage, and when strictures of the rectum formed they were dilated gradually with long bougies. In each case the duration of the illness was about two and one-half years before full recovery was established. They had, therefore, one case recovering after several severe surgical procedures, and the other without surgery, the disease lasting in each case practically the same length of time. It was hard to state which case received the proper treatment. They had had but one case recently at the Pennsylvania Hospital of fixation of the colon by bands of adhesions of the type that Mr. Lane so graphically described. This patient was also under the care of Dr. Gibbon. Two years previously she had had her breast amputated for carcinoma, and she entered the hospital with symptoms of partial obstruction of the bowel, which had existed for two months, with progressive loss in body weight and pain in the left iliac fossa, which was increased during defecation. The stools were ribbon-like. A diagnosis of carcinoma of the colon was made, probably of metastatic origin. There was no tumor of the colon on opening the abdomen, but the sigmoid flexure was found straightened and rigid by adhesion of its outer wall to the pelvic peritoneum above the brim of the true pelvis, and the omentum was attached in several places to the inner wall. Division of these adhesions restored the mobility of the sigmoid, and recovery was complete during the five months she was under observation. In connection with amebic dysentery, he desired to report another case which might perhaps illustrate the preformative stage of liver abscess. A young man of twenty-three had been out of sorts for about three weeks, with symptoms of mild gastric and intestinal disturbance. The movements were loose and averaged about two daily. Pain developed in the abdomen, which rapidly centered in the gall-bladder region, with marked tenderness and rigidity, elevation of temperature, and slight leucocytosis. The diagnosis was gastrointestinal catarrh with cholecystitis. On opening the abdomen a mild grade of adhesive peritonitis was found in the gall-bladder region, the transverse colon completely covering the gall-bladder and being adherent to the liver for a distance of three or four inches. On freeing these adhesions, the gall-bladder was found normal, but in the adjacent portion of overlying liver there was a tumor mass the size of a large walnut, infiltrating the liver, of a grayish color and fibrous in appearance. There was an encircling pinkish zone shading from the gray tumor to the normal liver substance. The picture presented was decidedly characteristic of gumma, but the diagnosis of syphilis was not established either by history, examination of a portion of the tumor removed, or by therapeutic test. Ten days after the operation the loose daily bowel movements changed into an active dysentery, and an examination of the stools revealed amebæ in large numbers. The dysentery promptly yielded to medical treatment, and the tumor of the liver gradually subsided. The recovery was uneventful, without further referable symptom to the liver. The microscopical examination of a section of the tumor removed showed only a fibrous hepatitis. The case was undoubtedly one of amebic dysentery from the start, and the question comes up, Was this fibrous hepatitis an early stage of liver abscess, which was absorbed by the treatment, or was it an intercurrent condition unconnected with the ameba?

Dr. Charles L. Gibson said that he would consider in his discussion only the surgical treatment of colitis. He was pleased to note the passing interest in the formation of an artificial anus; ten years ago this procedure would have been entertained, but not to-day. The serious consideration of making an artificial anus in the treatment of colitis did not last long. Its presence was as bad in many cases as the disease itself, and often did not cure the disease. This was merely a palliative method. It occurred to Dr. Gibson in studying the best way to relieve these cases that if they could apply some surgical measure, some simple, safe, and easy procedure for flushing the intestine from the beginning of the colon which would allow constant drainage, a great deal would be gained in the treatment of colitis. He had never felt that colonic irrigations were effective, except possibly temporarily. What was desired was some way to flush out the intestine thoroughly. He thought this might be done by imitating well-known procedures, making an opening into the intestine, placing in a tube, and, from time to time, flushing out the intestine with large quantities of water. This was the procedure which had been made so popular by Dr. Robert F. Weir, using the appendix as a point of entry into the intestine, and this was a simplification of Dr. Gibson's technique. In New York City alone this treatment had been successfully employed in over one hundred cases. This procedure was a great advance, and he was glad that they had given up the making of an artificial anus in the treatment of these cases.

Dr. Willy Meyer said that the cases that came to the surgeon after weeks, and sometimes years, of medical treatment were principally those of chronic dysentery, which might be tuberculous, amebic, or specific. In former years, when they made an artificial anus in the treatment of these cases, the patients were left in a terrible condition because of the fluid condition of the intestinal contents. A great advance had been made with the introduction of Dr. Gibson's and Dr. Weir's method, which produced a watertight entrance to the cecum and colon. The use of the appendix certainly was a great advance in the treatment of this class of cases. One should be very careful in making a differential diagnosis in patients who presented themselves with a bloody discharge. By means of the proctoscope or sigmoidoscope a diagnosis could, as a rule, be readily made. When patients suffered from repeated relapses operation was clearly indicated. Dr. Meyer used the McBurney incision. If the appendix appeared healthy, it should be used in preference to doing a cecostomy. In doing an appendicostomy it was very necessary in every instance to attach the root of the appendix to the parietal peritoneum. Flushing the large intestine was easily accomplished through a comparatively small appendix. Of course, its permeability must first be determined. If not permeable, a cecostomy must be performed. It made quite a difference whether one did an appendicostomy or a cecostomy. In the former operation it was hardly necessary for the patient to wear any dressings over the stump; it was only necessary to place a little gauze in the opening to guard against leakage. In the latter operation, however, a tube must be worn permanently. Dr. Meyer said that they certainly had made great advance in the treatment of such cases with the help of these two operations.

Dr. George E. Brewer said that the correction of chronic constipation relieved a great many of the nervous disorders, especially those that were associated with the various forms of toxemia. These were the cases that were very rebellious under medical treatment, and all should appreciate the importance of these colonic conditions that were associated with cases of chronic constipation and the consequent toxemia. Dr. Brewer said he would like to speak in reference to one point mentioned by Dr. Martin, the lesion he described as a thin vascular membranous veil covering the ascending colon and easily stripped therefrom. This he noticed several times. It showed conclusively that these adhesions might exist, and advance almost to a point of complete obstruction. In one patient he had under observation there were three or four distinct attacks of intestinal obstruction, with meteorism, vomiting, and acute abdominal pain. Certain medical measures relieved this patient, but the attacks were becoming so frequent that something had to be done surgically. The abdomen and the condition described by Dr. Martin was found. There was this thin vascular membranous veil covering the ascending colon and extending from the parietal peritoneum over the mesentery. This vascular membrane was removed without difficulty, being easily stripped therefrom, and this was followed by a complete relief of all the symptoms. Not infrequently had Dr. Brewer seen this same condition extending from the appendix over the cecum. This condition, he believed, might be one of the causes of chronic constipation and chronic toxemia. He believed, furthermore, that in not a few cases it might give rise to symptoms of obstruction.

Dr. James P. Tuttle said that he had been disappointed in that more attention had not been paid to the diagnosis of colonic disease, especially in regard to the significance of the presence of blood, mucus, and pus in the colon. He felt that, in the large majority of the malignant conditions connected with the rectum and colon, the condition became incurable, because the existing constipation or diarrhea was improved under treatment, and the real condition was not suspected. As Dr. Weber had stated, most physicians delayed the diagnosis of tumor or cancer of the bowel until obstruction took place, or a stasis of the fecal material occurred. The first symptoms of neoplasm were diarrhea, borborygmi, cramps; these symptoms appeared even before the appearance of blood, mucus, and pus, and evidenced simply the existing condition by little nagging pains in the bowels, which the physician thought to be nothing but an intestinal toxemia. The diagnostic methods should be studied more. The stools and urine should be more often examined, because often they revealed much of value. Another condition Dr. Martin referred to which interested Dr. Tuttle very much was coloptosis or enteroptosis. He was an advocate of fixation in these cases; on eight or ten occasions he had fixed the transverse colon after it had prolapsed into the pelvis, and with excellent results in all the cases. It was not a difficult operation, and the condition described was frequently one of the causes of constipation. Lane's work had interested him very much, and Dr. Tuttle had been given an opportunity to see fifteen of his cases. He thought that the lower colon had been much maligned, especially in the statement that there was no use for it except as a sewer. He believed it had an important function in the absorption of fats. Lane's cases were not done in private practice—they were experimental studies. He did an ileosigmoidostomy; he left the colon in. Fecal matter backed into the colon from below, or came in from above, and the patients suffered from a worse toxemia than before. Lane then planned to take out the colon, an operation of no great difficulty. The individuals were a sorry lot, with putty-like skins, with autointoxication symptoms and countenances; these fifteen cases composed that lot. Dr. Tuttle wished it to be understood that he did not recommend appendicostomy in the treatment of all cases of amebic dysentery. Over fifty per cent. of these cases could be cured by local measures. He wished to endorse what Dr. Weber had stated in regard to the use of bismuth; it was superior to ipecac and other remedies used, but it should be given in an enteric capsule. With regard to the irrigations with the patient in the knee-chest position, or in Matthew's posture, it sometimes happened that the remedies employed did not seem to reach the amebæ; in such cases excellent results would follow pouring into the patient's rectum two quarts of coal oil.

MEDICAL SOCIETY OF THE COUNTY OF KINGS.

Stated Meeting, Held November 15, 1909.

Dr. J. M. Van Cott in the Chair.

The Infectiousness and Contagiosity of Acute Poliomyelitis.—Dr. Le Grand Kerr of Brooklyn read this paper. He said that the occurrence of poliomyelitis in epidemics clearly established its infectiousness. The question then arose, Was it possible in a given epidemic to establish a relationship between the different cases, either through the agency of direct contact or otherwise? In the previous epidemics no systematized record had been made of the general distribution of the cases or their relation to one another. The speaker has made a careful investigation of sixty-five cases that he had personally observed. The first fifty-three of these had occurred in the Brownsville section of the borough of Brooklyn, city of New York, and had been limited to an area of thirty-four city blocks in one direction and eighteen blocks in another (approximately one mile by one mile and a half). August 3 was the date of the beginning of the epidemic, and the last case seen in this particular area had taken suddenly sick on September 4. Twelve cases had been studied in districts remote from the Brownsville section. These districts were from one to seven and a half miles from Brownsville. The parents of case 59 had been in the habit of frequently visiting the section in which cases 54 and 56 occurred, but had known of no direct contact. Cases 60 and 61 had been frequently in contact with the Brownsville section, the families exchanging visits, but there had been no history of direct contact with sick children. No definite history of exposure had been obtained. The parents of seven of the cases had been positive that their children had not been in direct contact with an affected child, and had not recently visited a section known to be affected. In seven instances there had been cases that developed in the same house in which had been other cases, but in different apartments, and in every instance the families had visited freely. The second cases had followed the first ones at the following intervals: In 3 days, 1; in 7 days, 3; in 8 days, 1; in 9 days, 1; in 11 days, 1. In twenty-three instances cases had occurred among children living in the same block (exclusive of the cases occurring in the same house), and in only nine instances did the families visit one another. The children mixed freely in the street. In the determination of the infectious or contagious nature of the disease the following factors were considered: Individual susceptibility, acquired individual susceptibility, tissue susceptibility, and the probable nature of the microbe. Individual susceptibility was subject to the following factors: (a) Inheritance. There was nothing in the histories of any of the cases to suggest the probability of an inherited individual susceptibility. (b) Racial susceptibility. Fifty-four of the cases occurred in children of Hebrew parentage, but the possible import of this was offset by the further fact that the cases were at first limited to an area the population of which was almost exclusively Hebrew. After the disease had been observed outside of this area the racial character changed. Of the

children of American parentage there had been 7 cases; of German, 2; of Italian, 1; of the colored race, 1, and Hebrew, 1. (c) Familial susceptibility. Of the sixty-five cases there was but one instance in which more than one in a family were affected (cases 62 and 63), so that this factor seems to have no bearing. (d) Individual susceptibility. There seems to be clear evidence that there existed an individual susceptibility. This was borne out by the fact that in a very large proportion of instances but one child in a family was affected. In the large majority of instances the disease occurred before the end of the third year of life in fifty-nine out of sixty-five cases. The fact was to be noted that with increasing age in children there was a decreasing aptitude for all infections. Acquired individual susceptibility was due to several factors, as follows: (a) The results of previous disease. Four children had had rubeola, two weeks, one year, sixteen months, and seventeen months, respectively, before the onset of the poliomyelitis. Pertussis was present in one child. Tonsillitis developed with the onset of the poliomyelitis in four instances, lobar pneumonia in one, and gastroentritis in two. There was a history of bronchopneumonia having occurred previously in eighteen children from three months to two and a half years before the onset of the poliomyelitis. Such histories seemed to show that the influence of previous disease was negative. There was a preponderance of gastroenteric symptoms in the onset of the disease in this series. Thirty-two of the cases showed constipation, diarrhea, or vomiting, or a combination of these symptoms. Similar symptoms were the rule in the other acute infections of children. The histories of cases 62 and 63 were detailed. A family of two adults and four children had arrived from California on September 20, and had moved into a new detached, modern house. On October 9 an infant eight months old had a fall, and on the following day there were fever, vomiting, and constipation. On October 11 both lower extremities were paralyzed. The infant had been fed from birth on peptonized and then on sterilized milk. On October 17 a sister of this child, who was twelve years old, complained of headache, and on the following day had fever and malaise. These continued on the 19th. At 11 P. M., after having retired, she awoke unable to turn over in bed, and, calling for aid, it was discovered that both lower extremities were completely paralyzed. Before daybreak both arms were involved in the paralysis, and the voice was so weak that it was impossible to hear her. All four extremities became cold and cyanotic, particularly the left ones. The right side of the face also was paralyzed. There was slight effort of the chest muscles to carry on respiration. The bladder was full, the neck musculature was rigid, and any motion caused pain. Death took place at 11 P. M. that night from respiratory paralysis. This case was autopsied by Dr. Flexner and Dr. Kerr the following morning. These cases were instances of two cases developing after removal into an infected district, one probably from direct contact with her infant brother, but with hygienic surroundings ideal and the food, in at least one of them, sterile. (b) The result of injury. The occurrence of an injury might favor infection. This need not be local, for a decided shock to the entire body might result from such an injury. In this series there were histories of recent injuries in but four cases. It was impossible to estimate the injury of overexertion on the very young. It was known that bacteria had a decided tendency to settle in those parts that were functionally most active. (c) The result of malnutrition. In all of the infants under the age of one year the feeding was by breast, with the exception of two upon modified milk. All except one of the latter showed unmistakable, although slight, signs of rachitis. Of those children over one year of age thirty-one exhibited some of the bony changes of rickets. In its broadest sense rachitis was a disease of malnutrition in which the nervous system suffered as completely as did the bones and other tissues, and the rachitic age was the age in which there was a relatively great development of the nervous system. Interference at this age with nerve nutrition might determine to some extent the development and localization of future disease. (d) The result of general exhaustion. This factor would naturally be present after several days of hot or depressing weather. The past summer was peculiarly free from hot days, and particularly from a succession of them. There was, however, excessive dryness. This had been noted in previous epidemics. Tissue susceptibility might be: (1) Inherent. There was nothing in the histories of these cases to indicate this. (2) Acquired through the agencies of (a) injury. There was no history of a local injury. (b) Local exhaustion. (c) Local malnutrition. (d) Impairment of nerve supply. Excessive functional activity of a part favored the liability to disease, and local exhaustion, and subsequently the inability to perfectly resist microbic invasion. The cord was functionally more active in immature than in mature life, and was easily overtaxed and exhausted. (e) Local disease. This was absent in every case. The probable nature of the microbe—There was much to indicate that the offending agent was one of low virulence. In support of this was the fact that in this, as in other epidemics, there was a widespread distribution. The disease did not usually affect more than one child in a family, nor was the infection of adults of frequent occurrence. Its common occurrence after a heated term, and particularly after a prolonged dry spell, seemed to indicate either a low virulence of the agent which was unfavorably influenced by low temperature, or which was so low as to require the aid of the favoring factor of heat to give it its power. The indication seemed to be that it was carried by a third person, who remained healthy but who was capable under favoring circumstances of being the innocent agent in its spread. The speaker was convinced that in acute poliomyelitis we were dealing with a hematogenic infection of a microbic agent of low virulence, that this infection was engrafted upon a tissue susceptibility which was acquired through the agencies of local malnutrition, exhaustion, and nerve impairment, and that this local condition was dependent upon the two factors of functional activity and a general state of malnutrition, and that the most favoring factor of all was an individual susceptibility, over which we had absolutely no control.

THE PRACTITIONERS' SOCIETY OF NEW YORK.

Stated Meeting, Held December 3, 1909.

Tuberculous Osteomyelitis of the Right Metatarsals.—Dr. V. P. Gibney showed a patient who had been suffering from tuberculous osteomyelitis of the right metatarsal bones, and in addition had shown signs of pulmonary and laryngeal involvement. The patient came to him for the first time in January, 1908, but had been receiving treatment elsewhere for some months previous, the foot having been put up in a plaster cast. The *x*-ray showed rarefaction of four of the metatarsals and without further treatment the patient was sent to Saranac in the Adirondacks. He was told to come back later for further treatment, which he did on May 8, 1908. Incisions were then made over the diseased metatarsals, the bones scraped and then wiped with iodoform gauze, and the wounds closed without drainage. (Smears and cultures made at the time of the operation from the diseased tissue were negative.) The foot was then put up in a plaster cast and the patient sent to Denver as soon as his condition permitted him to travel. From Denver he went to the Adiron-

dacks and later took a European tour. He was now seen for the first time since his operation and was enjoying the best of health. His foot was perfect in function and form and he had had no symptoms of further trouble. The signs of tuberculous infection elsewhere had entirely disappeared and he might well be pronounced cured.

Dr. Gibney said further: "This case presented all the clinical features of a tuberculous osteomyelitis. The history which I have shows that in the early part of his laryngeal troubles, as furnished by Dr. Coakley, a smear was taken by his Brooklyn physician, and the bacilli of tuberculosis found. Dr. Brown of Saranac treated him one or two seasons, but I have been unable to get a report from this gentleman. His assistant writes me that he was under Dr. Brown's care. My own pathologist, Dr. Jeffries, reported merely necrotic tissue. This kind of a report is frequently sent in by a pathologist, and later, after a little further search, they find in this same tissue the bacilli. Dr. Coakley treated him for some time for this laryngeal tuberculosis, and insisted on my using chloroform rather than ether at the time of the operation."

Dr. J. D. Bryant asked how much the constitutional treatment had to do with the cure of the local condition in the foot, and whether one should begin with the constitutional treatment in such cases or first operate on the local condition.

Dr. Gibney, in reply, said that it depended on many things, such as the patient's occupation, financial circumstances, etc., but that he should always have the proper general treatment if possible, depending on the severity of the case. In operating on such cases he advised closure of the wound without drainage, since cold abscesses were very frequently sterile and drainage only increased the danger of secondary infection.

Sarcoma of the Ankle.—Dr. Joseph D. Bryant reported this case. The patient was a policeman, forty-eight years of age, who had always enjoyed good health until the present illness. Twenty-seven years ago he was struck on the right ankle by a steel girder, but there was no fracture and the skin was not broken. Twenty years ago he slipped while getting off a car and received a lacerated wound of the lower right shin, extending to the bone. This was sutured with good result. Six years ago he slipped and sprained the right ankle and was unable to walk for several weeks. In February, 1908, the patient fell and injured his right ankle and was unable to stand on account of the pain. He was removed to a hospital and remained there two weeks with his foot and ankle in a plaster cast. Later he returned to police duty, but was forced to favor his right leg and complained that prolonged standing caused aching pain at the location of the callus at the junction of the middle and lower thirds. The last injury occurred in March, 1909, and was the result of a sprain while walking on a smooth pavement. After the injury he was unable to stand on the right foot and was taken home in a cab. The foot and leg swelled rapidly and he suffered great pain. He was treated for rheumatism for ten days and then the leg was splinted for two weeks. This treatment affording no relief, the foot and ankle were put up in a plaster cast and remained so for seven weeks. During this period he was never entirely free from pain and on removal of the cast was unable to stand on account of pain across the dorsum of the foot. He was able to move about with the aid of crutches, but could put no weight on the foot without suffering great pain as long as the foot was extended. Flexion of the foot to a right angle with the leg caused great pain. Since this last accident there had been constant redness of the lower third of the right leg and ankle, with some swelling and tenderness. This swelling had been increasing for the past few months. On admission to the hospital he complained of pain in the right ankle upon attempting to stand, loss of motion in the right ankle, and swelling and redness of the lower third of the right leg. The physical examination was negative, except for the local condition. The skin over the right leg was dusky red from the knee to the ankle, the lower third was much swollen, and an ovoid tumor was present on the inner side of this part of the leg. The skin over this region was very red, the leg pitted on pressure, and fluctuation was present on the inner side of the tumor. The tibia in its lower third presented some irregularities on the anteromesial aspect, with apparent loss of substance. The nodular irregularities felt like callus formation. The right ankle was swollen and dusky red, but extension of the foot was practically normal. Flexion was restricted and caused pain over the dorsum. Inversion and eversion were restricted and soft crepitation was felt in the ankle on manipulation. There were no palpable lymph nodes in the right leg. The urinary examination showed no albumin, but 0.9 per cent. of sugar. The patient was placed on antidiabetic diet on November 25 and again on November 29 was found to be sugar free and remained so. Blood examination showed white cells, 12,800, with 62 per cent. of polymorphonuclear cells, 28 per cent. large and small lymphocytes, and 10 per cent. transitionals and other mononuclear forms. The Wassermann reaction was negative, but the von Pirquet test with 25 per cent. tuberculin gave a slight reaction. On November 16 fluid was aspirated from the tumor mass and smears made from this showed many red blood cells, but no microorganisms. Cultures were made, but remained sterile. The patient was operated upon November 22, 1909, and an incision four inches long was made over the most prominent portion of the tumor on the inner surface of the tibia in the lower third. This incision was carried down through the membranous shell, following which about ʒiii of bloody fluid containing fat globules escaped. Some of the fluid was collected for examination. Upon the introduction of the finger it was found that the tumor was divided into six or seven cavities containing bloody fluid (resembling a multilocular cyst). By means of a chisel, portions of tibia were removed for examination. In all the cavity held about ʒviii of fluid, and extended completely through the tibia. The tissue removed at the operation proved on examination to be giant-cell sarcoma. The examination of the fluid showed red blood cells, fat globules, large flat crystals, and no bacteria.

Facial Hemiatrophy in a Child.—Dr. M. Allen Starr showed two photographs of a patient suffering from facial hemiatrophy which had been sent to him by Dr. Fiaschi of Sydney, Australia, the interesting fact being that the patient was now only eight years old and the disease began at the age of six after an attack of whooping cough. The atrophy involved the whole right side of the face from the supraorbital ridge to the lower border of the inferior maxilla, and had increased quite rapidly. The disease was not very uncommon among young adults, but Dr. Starr had been unable to find any record of a case in a young child.

Noma in Typhoid Fever.—Dr. Francis P. Kinnicutt reported the following case of fatal noma, developing on the thirty-fourth day of typhoid fever. He reported it on account of the very rare occurrence of noma in typhoid fever. The patient was a girl of eleven years, suffering from typhoid, who was admitted to his wards in the Presbyterian Hospital on the twelfth day

of the disease. Blood cultures were positive; Widal was negative at first, but later was positive. The patient was taking a fairly large amount of nourishment, 1,700 or 1,800 calories daily, of a semi-soft diet. On the thirty-fourth day of the disease the patient's temperature was normal for the first time, but she complained of toothache. Examination revealed a decayed tooth which was ulcerated about the base. The tooth was extracted, but the ulcer spread over the gum, the sublingual tissues, and the inner surface of the cheek. Later the ulcer perforated the cheek and rapidly destroyed a large portion of its tissues. The patient died on the tenth day after the development of the necrotic process, no treatment availing to arrest its progress. Agglutinins were entirely absent in the tenth dilution, but opsonins were present, as shown by the active phagocytosis and an opsonic index of 1.3 for staphylococcus. Pure cultures could not be obtained from the ulcerated area. Many organisms were present, the staphylococcus, streptococcus, and pseudo-diphtheria bacillus predominating. Stock vaccines of combined staphylococcus and streptococcus were given and the leucocytes rose from 10,000 to 17,000, with a marked increase in the polymorphonuclear forms, without influence, however, upon the rapid progress of the disease.

Radium as a Specific in Giant Cell Sarcoma.—Dr. Robert Abbe read this paper. (See page 1.)

Dr. Prudden remarked that it was an unfortunate classification that placed giant-cell sarcoma with general sarcomata, since the former were so specialized that some pathologists refused to include them with the truly malignant sarcomata. They might in time, however, become malignant.

Dr. J. D. Bryant said that there had been several cases of epulis in his service at Bellevue Hospital, the surgical removal of which had resulted in permanent cure. He asked Dr. Abbe if, in his opinion, the case of sarcoma which he had reported was a suitable one for radium treatment and suggested that he give the patient the necessary treatments.

Dr. Abbe thought the patient would respond to the treatment and said that he would be glad to give the necessary treatments and report the result at a later meeting.

Dr. Charles L. Dana asked why the *x*-ray men now disapproved of the use of radium.

Dr. Abbe, in reply, said that he thought the latter had given it up because they had neither studied its action carefully nor had been able to acquire a sufficient amount of the substance to obtain definite results. Radium probably acted similarly to the *x*-ray, but was much better in some cases. It had never failed to produce retrogression of certain sarcomatous tissue and nothing in surgery would compare with the specificity of its action except mercury and the iodides in syphilitic tumors. A wart, in a single treatment of one-half hour, would retrograde, not by caustic, cautery, or any chemical action, and disappeared entirely. It did not destroy tissues, though it might bring about necrosis by prolonged action; rather it caused a retrogression of the unnatural growth. Practically all cases of superficial epithelioma would disappear in a single treatment of from one-half to one hour's duration. There had been many failures in the treatment of carcinoma with radium, carcinoma of the tongue being especially refractory to this treatment. Dr. Abbe also spoke of the source of radium and pointed out the scarcity of pitchblende—its principal source. This substance yielded a refuse after the uranium had been extracted for the glass industry in Bohemia and the supply was very limited.

State Medical Licensing Boards.

STATE BOARD EXAMINATION QUESTIONS.

Idaho State Medical Licensing Board.

Boise, October 5 and 6, 1909.

ANATOMY.

1. Give the deep and superficial origin, course, and distribution of the pneumogastric nerve.
2. What constitutes the brachial plexus?
3. Give the origin, insertion, and nerve supply of the (a) longest and (b) shortest muscle in the body.
4. Name the flexor muscles of the forearm and describe one of them.
5. Describe the sternum, its articulations, and the important muscles attached to it.

HISTOLOGY.

1. From what primary layer is the nervous system developed? The peritoneum? The mucous membrane? The kidneys? The teeth?
2. What are the following: Corpus luteum? Macula lutea? Loop of Henle? Paccinian bodies? Stomata?
3. Describe the structure of the thyroid gland.
4. Mention all the histological bodies found in normal blood.
5. Name the layers of the retina.

PHYSIOLOGY.

1. Name the reflex centers of the medulla oblongata.
2. Is there any localization in the cerebellar cortex?
3. Name and give the location of the several sympathetic ganglia.
4. Name the principal secreting organs and the general types of structure.
5. What change takes place in the blood during its passage through the capillaries of the lungs?
6. Define external and internal secretions, and give an example of each.
7. Define proteoses and peptones, and say by what process those products are evolved during digestion.
8. Describe the structure of the uterus.
9. Give all the causes of contraction of the pupil.
10. Describe the act of deglutition. By what nerve centers is the process controlled?

CHEMISTRY AND TOXICOLOGY.

1. Give the chemical name and formula of (*a*) common salt, (*b*) marble, (*c*) plaster-of-paris, (*d*) borax, (*e*) blue vitriol, (*f*) sulphate of iron.
2. Give the symbol, atomic weight, and valence of five non-metals and of five metals.
3. Define molecular weight and molecular volume. Give an example of each.
4. Describe two experiments showing the difference between mechanical and chemical action.
5. Which is the most abundant element? Name the elements represented by the following symbols: K, Na, Ni, Si, Sb, S, Mg, Pb, Cu, Hg, Ag, Co, Mn, F, P.
6. How may poisons be classified? Give the manner of action of each class.
7. What is the difference between ptomains and leucomains? Give example of each.
8. Describe symptoms of toxic doses of strychnine, morphine, strophanthus, hydrocyanic acid, and aconite.
9. What antidotes should be used in phosphorus poisoning? Explain the action of each.
10. What is the chemical treatment for carbolic acid poisoning?

PATHOLOGY.

1. Define and describe thrombosis, embolism, metastasis, necrosis.
2. What is amyloid degeneration? In what organs does it generally occur?
3. Describe the process of parenchymatous inflammation.
4. Decribe the bacillus of tuberculosis. Describe a tubercle.
5. State the pathology of fibrinous or lobar pneumonia.
6. Give the pathological lesions of typhoid fever.
7. Give the pathology of chronic interstitial nephritis.
8. Describe the skin lesions occurring in psoriasis.
9. Locomotor ataxia; give its pathology.
10. What changes occur in the red blood corpuscles in progressive pernicious anemia?

DIAGNOSIS.

1. Tuberculin tests; give description of, uses, and results.

2. Give diagnosis of acute pancreatitis.
3. Differentiate cholecystitis and cholangitis.
4. Differentiate nephrolithiasis, chronic parenchymatous nephritis, and chronic interstitial nephritis.
5. Give blood findings in anemia.
6. Name three diseases caused by microorganisms, describe each organism, and give method of staining.
7. Differentiate between chronic pneumonia and tuberculosis of the lungs.
8. Give concise description of the heart murmurs, where found.
9. Differentiate between cerebral and gastric vomiting.
10. (*a*) Describe Hutchinson's teeth and state in what disease they are most commonly found. (*b*) What is Babinski's sign? (*c*) Koplik's spots? (*d*) Cheyne-Stokes respiration; when found?

THEORY AND PRACTICE.

1. Give methods of feeding infants who are deprived of mother's milk.
2. Stomatitis, varieties, symptoms, diagnosis, and treatment.
3. Give short description of serum therapy and name diseases in which it has been successfully employed.
4. Give etiology, symptoms, prognosis, diagnosis, and treatment of acute ileocolitis.
5. Give etiology, symptoms, diagnosis, prognosis, complications, and treatment of typhoid fever.
6. Same of gonorrheal arthritis.
7. Same of tabes dorsalis.
8. Same of cerebrospinal meningitis, including microscopic specimen; how obtained and findings.
9. Describe bronchiectasis, give symptoms, physical signs, and treatment.
10. Give etiology, symptoms, prognosis, diagnosis, and treatment of rachitis.

OBSTETRICS.

1. Give diagnosis of cystic degeneration of the chorion; treatment; prognosis.
2. Give mechanism of labor, vertex presentation.
3. Give presumptive and positive signs of pregnancy.
4. Give management of lateral placenta prævia.
5. Give management of threatened abortion; treatment of complete abortion.
6. How diagnose ectopic pregnancy?
7. What conditions would necessitate (*a*) version, (*b*) Cesarean section, (*c*) forceps delivery?
8. Why is it necessary hastily to deliver the head in breech or foot presentations?
9. What is the cause of phlegmasia alba dolens?
10. How diagnose and treat invertion of the uterus?

GYNECOLOGY.

1. Give the etiology, symptoms, and treatment of acute pelvic peritonitis.
2. Give the etiology, symptoms, and treatment of acute ovaritis.
3. Make a differential diagnosis between ascites and ovarian cyst.
4. Give the symptoms and treatment of membranous dysmenorrhea.
5. Define and give the etiology and symptoms of pelvic hematocele.
6. Give the etiology, symptoms, and treatment of abscess of the vulvovaginal gland.
7. Describe the symptoms of salpingitis. Name the varieties of salpingitis according to the tubal contents.
8. Give the symptoms and treatment of urethral caruncle.
9. Describe the symptoms and treatment of a rectovaginal fistula.
10. Give the symptoms and treatment of gonorrheal vaginitis. Name the complications.

SURGERY.

1. Define asepsis; mention a few of the best antiseptics.
2. Mention five common suture materials and tissues best joined by each.
3. Write less than two hundred words, stating your practice with regard to drainage.
4. Give treatment for paronychia, hordeolum, empyema.
5. How would you diagnose cystic calculi?
6. Give the differential diagnosis of appendicitis.
7. How treat peritonitis?
8. Give treatment for ingrowing toenail; treatment for actinomycosis.
9. Mention surgical complications of typhoid fever.
10. What is appendicostomy, dactylitis, osteomyelitis, Dubois' abscess, hysterotrachelorrhaphy?

HYGIENE.

1. Name the principal constituents of soil and its physical properties.
2. Define tilth, marl, loam, humus, peat, muck, and state which of those soils will retain the greatest amount of water, and which is most inimical to pathogenic organisms.
3. To what average depth is soil self-purifying, by what natural agents is the work accomplished, and how do the dwellers on the soil retard it?
4. Name the different sources of our water supply and its sanitary classification.
5. How may a well be polluted by a cesspool on a lower level or remain unaffected by one on higher ground? Answer by diagram if you wish.
6. Describe an ordinary filter bed for the purification of water, and say what is the fundamental principle of Dibdin's bacteria beds, and Cameron's septic tank.
7. Do we inspire and expire microorganisms?
8. Describe the atmospheric conditions desirable for the support of human life.
9. What effect upon the blood results from the inhalation of carbon monoxide and what per cent. by volume is fatal to animal life?
10. Tabulate the conditions of hygienic interest with regard to various employments.

ANSWERS TO STATE BOARD EXAMINATION QUESTIONS.

IDAHO STATE MEDICAL LICENSING BOARD.

Boise, October 5 and 6, 1909.

ANATOMY.

1. PNEUMOGASTRIC NERVE. *Superficial origin:* Groove between restiform and olivary bodies. *Deep origin:* Nuclei in floor of fourth ventricle. *Course:* Outward across the flocculus, to jugular foramen through which it passes, here it is joined by the accessory portion of the spinal accessory nerve. As it goes down the neck it lies in front of the rectus capitis anticus major and longus colli muscles. It passes in the carotid sheath behind and between the artery and vein. In the thorax the nerve on each side runs a different course. The *right* passes between the subclavian artery and vein, by side of trachea to root of lung, behind esophagus, through esophageal opening in diaphragm to posterior surface of stomach. The *left* passes between the subclavian and carotid arteries, in front of arch of aorta to root of lung, along anterior surface of esophagus, through diaphragm, to anterior surface of stomach. *Distribution* is shown by the names of the branches: Meningeal, auricular, pharyngeal, superior and inferior laryngeal, cardiac, pulmonary, esophageal, and gastric.

2. The *brachial plexus* is formed by the union and subsequent division of the anterior divisions of the fifth, sixth, seventh, and eighth cervical and the first dorsal nerves. The union of the fifth and sixth makes the upper trunk; the seventh forms the middle trunk, and the eighth cervical and first dorsal make the lower trunk. Each of these trunks is divided into an anterior and a posterior branch. The anterior branches, from the upper and middle trunks, make the upper or outer cord of the plexus; the anterior branch of the lower trunk becomes the lower or inner cord; the three posterior branches unite to form the posterior or middle cord. The plexus lies between the Scalenus anticus and medius. The *branches* are: (1) Above the clavicle; communicating, muscular, posterior thoracic, and suprascapular. (2) *From outer cord:* External anterior thoracic, musculocutaneous, and outer head of median. (3) *From inner cord:* Internal anterior thoracic, lesser internal cutaneous, ulnar, and inner head of median. (4) *From posterior cord:* Subscapular, circumflex, and musculospiral.

3. *Longest muscle* in body is SARTORIUS. *Origin:* Anterior superior spine of ilium, and notch below. *Insertion:* Inner and upper part of shaft of tibia. *Nerve supply:* Anterior crural. *Shortest muscle* is probably STAPEDIUS. Origin: Pyramid of tympanum. *Insertion:* Neck of stapes. *Nerve supply:* Facial.

4. Biceps, brachialis anticus, supinator longus, pronator radii teres. The *Supinator longus* arises from the upper two-thirds of the external supracondylar ridge of the humerus, and is inserted into outer side of the base of the styloid process of the radius. It is superficial for most of its extent; it is supplied by the musculospiral nerve. Besides being a flexor of the forearm, this muscle acts both as a pronator and supinator; it tends to bring the bones of the forearm into a position midway between pronation and supination.

5. The STERNUM is a flat, narrow bone, situated in the

median line of the front of the thorax. It consists of three portions: Manubrium, gladiolus, and ensiform. It is about seven inches long. At the junction of the first two pieces is the angle of Ludovic; and here the second costal cartilage joins the bone. It articulates with the clavicle and seven costal cartilages on each side. Muscles attached are: Pectoralis major, sternomastoid, sternohyoid, sternothyroid, diaphragm, triangularis sterni, and aponeuroses of external oblique, internal oblique, rectus abdominis, and transversalis.

HISTOLOGY.

1. The nervous system is developed from the epiblast; the peritoneum, from mesoblast; mucous membrane, from epiblast and hypoblast; kidneys, from mesoblast; teeth, the enamel from the epiblast, dentine from the mesoblast.

2. *Corpus luteum* is a yellow body formed in the ovary at the site where an ovum has been discharged from a Graafian follicle. *Macula lutea* is a yellow depressed spot at the center of the retina; vision is most acute here. *Loop of Henle* is a part of the convoluted uriniferous tubule of the kidney. *Pacinian bodies* are ovoid, laminated bodies surrounding the termination of certain nerves in the skin and mesentery and corpora cavernosa. *Stomata* are minute orifices between endothelial (and other) cells.

3. The thyroid gland "is surrounded by a capsule that sends in trabeculæ, which divide the gland into lobes and lobules. These divisions are irregular, and the lobules are composed of a number of short tubules, sometimes called follicles. Each tubule is lined by cuboidal epithelial cells that rest upon a basement membrane; outside of this is the intralobular, or intertubular, connective tissue that supports the blood-vessels. In the tubules is seen a peculiar, homogeneous substance, the colloid substance, that is supposedly the result of the activity of the cells. It has a yellowish color, and as blood cells are frequently seen in it, the color may be due to the hemoglobin from these."—(Radasch's *Compend of Histology.*)

4. Red corpuscles: white corpuscles (small mononuclear, large mononuclear, transitional, polynuclear, esinophile); platelets.

5. (1) Layer of pigment cells; (2) layer of rods and cones; (3) the external limiting membrane; (4) the outer nuclear, or granular, layer; (5) the outer molecular, or reticular, layer; (6) the inner nuclear, or granular, layer; (7) the inner molecular or reticular layer; (8) the layer of ganglion cells; (9) the layer of nerve fibers; and (10) the internal limiting membrane.

PHYSIOLOGY.

1. (1) Center for mastication, (2) for secretion of saliva, (3) for sucking, (4) for deglution, (5) for vomiting, (6) for voice, (7) center for expression, (8) cardiac centers, (9) respiratory centers, (10) vasomotor centers.

2. Strictly speaking, there is no localization.

3. *Ganglion of Ribes*, on anterior communicating artery. *Superior cervical*, in front of the transverse processes of the second and third cervical vertebræ. *Middle cervical*, opposite sixth or seventh cervical vertebra, and in relation with inferior thyroid artery. *Inferior cervical*, over back of first rib, and beneath vertebral artery. *First thoracic*, beneath head of first rib; sometimes blends with inferior cervical. *Second to eleventh thoracic*, on heads of ribs, under cover of pleura. *Twelfth thoracic*, on side of twelfth thoracic vertebræ, behind diaphragm. *Four lumbar ganglia*, in front of bodies of lumbar vertebræ, on inner side of psoas, and being overlapped by aorta and inferior vena cava. *Four sacrol ganglia*, on inner side of anterior sacral foramina. *Ganglion impar*, in front of coccyx. Also *ophthalmio ganglia*, at back of orbit. *Sphenopalatino*, in sphenomaxillary fossa. *Otic*, below foramen ovale. *Submaxillary*, above submaxillary gland and behind mylohyoid muscle.

4. Liver, pancreas, salivary glands, intestinal glands; sweat, and sebacceous glands; testes, Cowper's glands, mammary glands; lacrymal glands; small gland in respiratory tract; ductless glands (spleen, thyroid, thymus, and suprarenals).

General types of structure: I. SIMPLE GLANDS.—Duct undivided. (*a*) *Simple tubular:* Undilated at end. (*b*) *Simple acinous (alveolar or saccular):* Dilated at end. II. COMPOUND GLANDS.—Duct divided. (*a*) *Compound tubulor:* Branched elongated tubes, no acini. (*b*) *Compound acinous or alveolar (racemose glands)*, branched duct with saccular acini on terminal branches. (*c*) *Acinotubular.*—Branched duct, with elongated narrow acini on terminal branches.

5. (1) The giving up of the CO_2 by the venous blood, (2) the absorption of oxygen during inspiration, (3) cooling of the blood, (4) loss of a small amount of watery vapor, (5) the color becomes red.

6. *External secretions* are such as are carried off from the secreting gland by a duct; as, the bile. *Internal secretions* are such as are not carried off by a duct, but are discharged into the blood or lymph; as, the secretion of the thyroid (or other ductless glands).

7. *Proteoses* are intermediate products between proteids and peptones. *Peptones* are the final product of digestion of proteids. They are both evolved by the action of the pepsin of the gastric juice, and the trypsin of the pancreatic juice, during the digestion of proteids.

8. See Cunningham's "Anatomy" (1909), page 1187; or Gray's "Anatomy" (1908), page 1498.

9. (1) Stimulation by light; (2) stimulation of third cranial nerve; (3) paralysis of cervical sympathetic; (4) accommodation for near objects; (5) sleep; (6) myotic drugs, such as opium; (7) turning inwards of the eyeball.

10. *Deglutition:* "The masticated food is gathered up by the tongue and formed into a bolus between the tongue and the hard palate. The tongue is then pressed from before backwards against the roof of the mouth, and the bolus slips back, through the fauces, and is ultimately grasped by the pharyngeal muscles, and passed into the esophagus. The act of deglutition is divided into three stages: "The first stage is a voluntary act, by which the food is carried back to the anterior pillars of the fauces. The second stage consists in the passage of the bolus from the anterior pillars of the fauces to the commencement of the esophagus; this is a reflex act, and is performed very rapidly, as the food has to pass over the opening of the larynx. As soon as the bolus arrives at the isthmus of the fauces, the pharynx is prepared for its reception. The hyoid bone is drawn forwards and upwards, so that the larynx is protected by the base of the tongue, which projects over it; the epiglottis being closed at the same time, and the vocal cords approximated so as to close the rima glottidis. The pharynx itself is shortened and drawn forward by the contraction of the palato-pharyngei muscles; the soft palate is also raised and made tense, thus cutting off the upper part of the pharynx and posterior nares, and forming an incline under which the bolus is passed into the pharynx. This passage is effected by the elevation of the hyoid bone and the base of the tongue, and the simultaneous contraction of the pillars of the fauces. The bolus is then seized and carried rapidly down past the larynx by the pharyngeal constrictors. The third stage of the act of deglutition is due to the peristaltic contractions of the esophagus." The nerve centers are in the medulla.

CHEMISTRY AND TOXICOLOGY.

1.

	CHEMICAL NAME.	FORMULA.
(*a*) Common salt.....	Sodium chloride	NaCl
(*b*) Marble	Calcium carbonate	$CaCO_3$
(*c*) Plaster of Paris....	Calcium sulphate	$CaSO_4$
(*d*) Borax	Disodic tetraborate	$Na_2B_4O_7$
(*e*) Blue vitriol	Cupic sulphate	$CuSO_4$
(*f*) Sulphate of iron....	Ferrous sulphate	$FeSO_4$

2.

	SYMBOL.	ATOMIC WEIGHT.	VALENCE.
Five non-metals:			
1. Hydrogen	H	1	1
2. Oxygen	O	16	2
3. Nitrogen	N	14	3 or 5
4. Fluorine	F	19	1
5. Chlorine	Cl	35.5	1
Five metals:			
1. Mercury	Hg	200	2
2. Copper	Cu	63	2
3. Aluminum	Al	27	3
4. Gold	Au	197	1 or 3
5. Silver	Ag	108	1

3. *Molecular weight* is the weight of a molecule of a substance as compared with the weight of an atom of hydrogen. It may also be said to be the sum of the weights of the atoms composing the molecule. Thus, the molecule weight of sulphuric acid, H_2SO_4 is $(2+32+64)$, that is, 98; or 98 times the weight of an atom of hydrogen. *Molecule volume* is the molecular weight divided by the specific gravity.

4. "When a cylinder of lime is strongly heated it becomes white hot and emits light; it is still lime, however, after the action of the heat, as it was before. This is a physical phenomenon. If, now, we throw this lime into

hydrochloric acid it disappears, and, after the action has been completed, we find neither lime nor hydrochloric acid, but two new substances, one a solid, called calcium chlorid, the other a liquid—water; both of which differ in their composition from the original substances, which have disappeared. This is a chemical phenomenon."

5. The most abundant element is oxygen. K is potassium; Na, sodium; Ni, nickel; Si, silicon; Sb, antimony; S, sulphur; Mg, magnesium; Pb, lead; Cu, copper; Hg. mercury; Ag, silver; Co, cobalt; Mn, manganese; F, fluorine; P, phosphorus.

6. Poisons may be classified as: (1) Mineral, (2) vegetable, (3) animal, and (4) synthetic.

7. *Ptomains* are basic, nitrogenous compounds, produced from protein material by the bacteria which cause putrefaction. *Examples:* Cadaverin, and putrescin. *Leucomains* are similar substances produced in living animals during normal metabolism. *Examples:* Xanthin and hypoxanthin.

8. The *symptoms of strychnine poisoning* are as follows: A sense of suffocation, thirst, tetanic spasms, usually opisthotonos, sometimes emprosthotonos, occasionally vomiting, contraction of the pupils during the spasms, and death, either by asphyxia during a paroxysm or by exhaustion during a remission. The *symptoms of poisoning by morphine* are as follows: At first there is usually a period of excitation, marked by restlessness, great physical activity, loquacity, and hallucinations. The patient then becomes weary, dull, and drowsy; he yields to the desire for sleep, from which at first he may be roused. The lips are livid, the face pale, the pupils contracted, and the surface bathed in perspiration. The condition of somnolence rapidly passes into narcosis. The patient cannot be roused, and lies motionless and senseless, with completely relaxed muscles. The pulse, at first full and strong, becomes feeble, slow, irregular, and easily compressible; the respiration slow, shallow, stertorous, and accompanied by mucous râles. The patient rapidly becomes comatose, and in fatal cases, dies in from 45 minutes to 56 hours, usually in from 12 to 18 hours. *Strophanthus* causes: Nausea, colic, diarrhea, slow pulse, dyspnea, headache, vertigo, cold extremities, drowsiness, and syncope. *Hydrocyanic acid* causes: Constriction of throat, vertigo, mental confusion, loss of muscular power, quick pulse, slow respirations, tetanic convulsions, loss of control of sphincters, and paralysis. *Aconite* causes: Numbness and tingling, first of the mouth and fauces, later becoming general. Dryness and constriction in the throat. Persistent vomiting usually occurs, but is absent in some cases. There is diminished sensibility, with numbness, great muscular feebleness, giddiness, loss of speech, irregularity and failure of the heart's action.

9. Antidotes to phosphorus are: Old French oil of turpentine and potassium permanganate. The latter acts as an oxidizing agent. Fats and oils must not be given, as they would help in the absorption of the phosphorus.

10. For carbolic acid poisoning: Give sodium sulphate, or magnesium sulphate, or albumin; follow this with lavage. Alcohol is also recommended.

PATHOLOGY.

1. *Thrombosis* is the coagulation of the blood within the vessels during life. *Embolism* is the plugging of a blood-vessel by a foreign body. *Causes of thrombosis:* (1) Changes in the walls of the blood-vessels, due to the presence of infection or foreign bodies; (2) changes in the blood, whereby its tendency to coagulate is increased; (3) diminished rate of the blood flow, due to weak heart action or obstruction. *Embolism* is generally due to thrombi, but is also caused by fragments of vegetations or atheromatous or calcareous masses from the cardiac valves or the intima of the arteries; other causes are parasites, pieces of new growths, pigment granules, fluid fat, or air. *Metastasis* is the transfer of some pathological condition from one part of the body to another not immediately connected with it. *Necrosis* is the complete and permanent arrest of nutrition in a part; or local death of tissue.

2. *Amyloid degeneration* is a degenerative process in which the affected tissues have a whitish waxy appearance, due to the presence of a colorless, firm, translucent and lardaceous substance. With iodine it gives a blue stain. It generally occurs in: Liver, kidneys, spleen, lymphatic glands, intestines

3. *Parenchymatous inflammation* is the name occasionally given to an inflammatory process when it attacks the active cells and tissues of an organ; as in parenchymatous nephritis, where the renal epithelium is affected.

4. The tubercle bacillus is rod shaped, is from 1½ to 3½ mikrons in length, and about one-third to one-half a mikron in breadth, is a strict parasite, is not motile, and has no flagella; it has no spores, is non-liquefying, non-chromogenic, erobic, and acid-resisting. A *tubercle* is a small nodule, found in the lungs or other organs in cases of tuberculosis, but also found in other diseased conditions. It consists of three layers, the outer one consisting of lymphoid cells, the middle one of epitheloid cells, and the inner one of giant cells. These layers are squeezed or compressed into a firm mass, which may caseate or undergo other pathological processes. There is no blood supply to a tubercle.

5. See French's "Practice of Medicine" (1907), page 154; or Osler's "Practice of Medicine" (1909), page 170.

6. See French's "Practice of Medicine" (1907), page 70; or Osler's "Practice of Medicine" (1909), page 65.

7. See French's "Practice of Medicine" (1907), page 902; or Osler's "Practice of Medicine" (1909), page 695.

8. Round or oval red patches, covered with adherent, silvery, or gray scales; these occur chiefly on the extensor surfaces of elbow, knee, and limbs; also on scalp. There is more or less itching, and the condition is apt to be chronic. On removing the scales a red, punctate, bleeding surface is found.

9. See French's "Practice of Medicine" (1907), page 1047; or Osler's "Practice of Medicine" (1909), page 887.

10. (1) Diminution in number; (2) relative increase in amount of hemoglobin; (3) poikilocytosis; (4) some are nucleated; (5) variation in size.

DIAGNOSIS.

1. The *tuberculin test* consists in giving a hypodermic dose of 1 mg. of the fluid; if no reaction occurs in twenty-four hours, a dose of 2 mg. is given; if, again, there is no reaction in twenty-four hours, a dose of 3 mg. is given. The maximum dose is 10 mg. Its *use* is to aid in the diagnosis of tuberculosis. *Results:* It is said to be valuable; but some say it should never be used.

2. Pain in epigastrium, which is sudden and severe; vomiting; collapse; swelling and tenderness over epigastrium; and slight fever.

3. In *cholecystitis* are: Pain in and tenderness over gall-bladder; muscular rigidity; fever, rapid pulse, vomiting. In *cholangitis* the symptoms are much the same, but the pain is very much more severe, and radiates to right shoulder; the fever is also less.

4. *Neprolithiasis* is characterized by: Renal colic, with pain radiating to testicle; hematuria; tenderness over affected kidney; *x*-ray may show the calculus. This condition is not likely to be mistaken for the two forms of nephritis. In *chronic parenchymatous nephritis:* The urine is slightly diminished, turbid, has abundance of albumin, generally some blood, abundance of sediment, blood corpuscles, casts (especially fatty), diminished urea; may be cardiac hypertrophy; marked dropsy, and often uremia. In *chronic interstitial nephritis:* The urine is increased in quantity, pale, clear, of low specific gravity, little or no albumin, scanty sediment, few casts, diminished urea; the heart is hypertrophied, sometimes considerably; dropsy often absent till heart fails; uremia frequent.

5. In *secondary anemia:* (1) A diminution in the number of red corpuscles; (2) a diminution in the amount of hemoglobin, perhaps greater than that of the red corpuscles; (3) poikilocytosis, and variations in the size of the red corpuscles; (4) the presence of a few nucleated red corpuscles; (5) a moderate leucocytosis. In *pernicious anemia:* (1) A diminution in the number of red corpuscles; (2) a relative increase in the amount of hemoglobin; (3) poikilocytosis; (4) the presence of nucleated red cells; (5) variation in the size of the red cells; (6) the leucocytes *may* be diminished.

6. (1) TUBERCULOSIS. For *description* of bacillus, see above, PATHOLOGY, Question 4. For *staining* (in sputum): See French's "Practice of Medicine" (1907), page 1216. (2) GONORRHEA. The *Gonococcus* is a diplococcus with a special predilection for the mucous membrane of the urethra; it is sometimes found on the conjunctiva. The appearance is that of two coffee beans; the gonococcus is found in the pus cells, stains with ordinary anilin dyes, but not by Gram's method. It is erobic, and can be cultivated on human blood serum; it will not grow on gelatin, agar, bouillon, or potato. (3) DIPHTHERIA. The Klebs-Loeffler bacilli are from 2 to 6 mikrons in length and from 0.2 to 1.0 mikron in breadth; are slightly curved, and often have clubbed and rounded ends; occur either singly or in pairs, or in irregular groups, but do not form chains; they have no flagella, are non-motile, and erobic; they are noted for their pleomorphism; they do not stain uniformly, but stain well by Gram's method and very beautifully with Loeffler's alkaline-methylene blue.

7. The symptoms and physical signs of *lobar pneumonia* and *acute pneumonic phthisis* may be the same for the first

eight or ten days; at this period the fever in *pneumonia* drops by crisis; whereas in *phthisis* the fever continues for some time longer and the patient gets worse; the sputum contains tubercle bacilli and elastic fibers, and instead of retaining the rusty color it becomes purulent and greenish.

In *pneumonia*, the breathing is very rapid, the pulse-respiration rate is disturbed, the fever is usually high, and runs a regular course, crepitant râles are heard at first, then signs of consolidation follow, and crepitant râles again succeed. In *phthisis*, the breathing is hurried and there is dyspnea, the fever is often high, but does not run a regular course, at first the signs are those of bronchitis, followed by consolidation, a softening, or excavation in different parts of the lungs; sometimes there is nothing to be heard but scattered râles.

8. (1) A systolic murmur, soft and blowing, heard best at the apex, and transmitted to the left axilla and toward the angle of the left scapula, indicates mitral regurgitation. (2) A presystolic murmur, harsh and rough, heard best very near the apex, and not transmitted, denotes mitral stenosis. (3) A diastolic murmur, soft, heard best in the second right intercostal space, and transmitted down the sternum or toward the apex, denotes aortic regurgitation. (4) A systolic murmur, harsh, heard best in the second right intercostal space, and transmitted into the carotids, denotes aortic stenosis. (5) A systolic murmur, heard best over the lower end of the sternum, denotes tricuspid regurgitation. (6) A presystolic murmur, heard best over the ensiform cartilage, and not transmitted, denotes tricuspid stenosis. (7) A diastolic murmur, heard best in the second left intercostal space, denotes pulmonary regurgitation. (8) A systolic murmur, heard best in the second left intercostal space, and not transmitted to the large vessels of the neck, denotes pulmonary stenosis. (9) A murmur, usually systolic, soft, and blowing, heard best over the pulmonic area, associated with evidences of chlorosis or anemia, and affected by the position of the patient, is a hemic or functional murmur, and denotes as a rule an impoverished condition of the blood.

9. *Cerebral vomiting* is projectile in character, and is accompanied by little or no nausea, is continuous even after stomach is emptied; there is no salivation, no tenderness over liver or stomach. *Gastric vomiting* relieves the previous nausea, and returns on ingestion of food; salivation is present, also tenderness over liver and stomach.

10. (*a*) *Hutchinson's teeth* are notched and stunted in permanent dentition; found in hereditary syphilis.

(*b*) *Babinski's sign:* When the sole of the foot is tickled, the toes (particularly the great toe) are over-extended, and separated from one another. (In primary lateral sclerosis.)

(*c*) *Koplik's spots* are small red spots with a bluish central area, found on the buccal mucous membrane, in measles.

(*d*) In *Cheyne-Stokes respiration* the respirations gradually increase in volume and rapidity until they reach a climax, when they gradually subside, and finally cease for from ten to forty seconds, when the same cycle begins again. "In the majority of instances it is associated with apoplexy (toward the end), chronic nephritis (uremia), tumor of the brain, tuberculous meningitis, or degeneration of the heart muscle. Less frequently it is observed as a result of cardiac valvular defects and consequent embolism, diabetes, and certain acute diseases, notably typhoid, pneumonia, pertussis, cerebrospinal fever, scarlet fever, and septicemic conditions."—(Butler's *Diagnosis of Internal Medicine.*)

THEORY AND PRACTICE.

1. By wet nurse; by milk of cow or goat; by whole milk and its dilutions; by cream-milk mixture; by top-milk mixture; by cream-whey modifications; by milk modified with cereal decoctions or dextrinized gruels; by diluted condensed milk; by "laboratory milk," which may be gravity-separated or centrifuged; by peptonized milk; or by any of the numerous advertised substitutes.

2. See French's "Practice of Medicine" (1907), page 707; or Osler's "Practice of Medicine" (1909), page 434.

3. "*Serum therapy* depends upon the fundamental fact that a group of body cells—for example, those of the central nervous system—have a way of rising to the emergency when compelled to defend themselves against a group of foreign cells (*e.g.* tetanus bacilli) and of producing in excess substances antagonistic to such foreign cells or to their products. Such an antagonism is known as immunity. To be immune against a given cell is to possess the power of poisoning or dissolving that cell. This is known as antibacterial immunity. When the body is attacked, not by cell groups but by cellular products, such as toxins, another type of immunity is produced by virtue of which the blood of the immunized individual is able to neutralize and render inert the toxin molecules."—(*Reference Handbook of the Medical Sciences.*) Diseases in which it has been successfully employed are: Diphtheria, tetanus, snake-bites, and rabies.

4. See French's "Practice of Medicine" (1907), page 771; or Osler's "Practice of Medicine" (1909), page 508.

5. See French's "Practice of Medicine" (1907), page 65; or Osler's "Practice of Medicine" (1909), page 57.

6. See French's "Practice of Medicine" (1907), page 216; or Osler's "Practice of Medicine" (1909), page 282.

7. See French's "Practice of Medicine" (1907), page 1046; or Osler's "Practice of Medicine" (1909), page 886.

8. See French's "Practice of Medicine" (1907), page 139; or Osler's "Practice of Medicine" (1909), page 157.

10. See French's "Practice of Medicine" (1907), page 932; or Osler's "Practice of Medicine" (1909), page 426.

OBSTETRICS.

1. See Williams' "Obstetrics" (1909), page 576; or Hirst's "Obstetrics" (1909), page 116.

2. See Williams' "Obstetrics" (1909), page 254; or Hirst's "Obstetrics" (1909), page 395.

3. *Presumptive signs of pregnancy:* (1) Progressive enlargement of the uterus; (2) Hegar's sign; (3) Braxton Hick's sign; (4) uterine murmur; (5) cessation of menstruation; (6) changes in the breasts; (7) discoloration of the vagina and cervix; (8) pigmentation and striæ; (9) morning sickness. *Positive signs of pregnancy:* (1) Hearing the fetal heart sound; (2) active movements of the fetus; (3) ballottement; (4) outlining the fetus in whole or part by palpation; and (5) the umbilical or funic souffle.

4. See Williams' "Obstetrics" (1909), page 815; or Hirst's "Obstetrics" (1909), page 577.

5. See Williams' "Obstetrics" (1909), page 617; or Hirst's "Obstetrics" (1909), page 279.

6. See Williams' "Obstetrics" (1909), page 647; or Hirst's "Obstetrics" (1909), page 304.

7. (*a*) The *indications for podalic version* are: (1) In transverse presentations; (2) in placenta prævia; (3) in malpresentations of the head; (4) in simple flattened pelvis, and in minor degrees of pelvic contraction; (5) in prolapsed funis; (6) in sudden death of the mother; and (7) in any case where speedy delivery is imperative. (*b*) The *absolute indications for cesarean section* are: Extreme pelvic contraction or deformity in which delivery by forceps or version or symphyseotomy is impossible, and in which craniotomy is either impossible or would be more dangerous to the mother; the presence of extreme atresia of the vagina; rupture of the uterus; sudden maternal death. (*c*) *Indications for the use of forceps* are: "1. *Forces at fault:* Inertia uteri in the presence of conditions likely to jeopardize the interests of mother or child. (*a*) Impending exhaustion; (*b*) arrest of head, from feeble pains. 2. *Passages at fault:* Moderate narrowing, 3¼ to 3¾ inches, true conjugate; moderate obstruction in the soft parts. 3. *Passenger at fault:* A. Dystocia due to (*a*) occipito-posterior, (*b*) mento-anterior face, (*c*) breech arrested in cavity. B. Evidence of fetal exhaustion (pulse above 160 or below 100 per minute.) 4. *Accidental complications:* Hemorrhage; prolapsus funis; eclampsia. All acute or chronic diseases or complications in which immediate delivery is required in the interest of mother or child, or both." (From Jewett's *Practice of Obstetrics.*)

8. The head should be delivered promptly to avert the chance of the child being asphyxiated.

9. *Phlegmasia alba dolens* is a form of manifestation of puerperal sepsis in which there is a thrombosis of the iliac or femoral vein. Sometimes it occurs after a uterine phlebitis, in which clots are carried from the uterine sinuses to the hypogastric veins, where they cause obstruction to the blood flow in the crural veins. The trouble may also begin as a crural phlebitis. It is thus due either to cellulitis or to thrombosis. It usually appears about the third or fourth week of the puerperium.

10. See Williams' "Obstetrics" (1909), page 824; or Hirst's "Obstetrics" (1909), pages 614 and 616.

GYNECOLOGY.

1. ACUTE PELVIC PERITONITIS. *Etiology:* Infection. *Symptoms:* Intense and diffuse abdominal pain, tenderness, and distention; vomiting, constipation, elevation of the temperature (103°-104° F.), small, hard, rapid, and wiry pulse (120-140), and increased respiration (30-40) of a painful character are also present. The dorsal decubitus with the legs and thighs drawn up is assumed. The duration is from six to nine days and the prognosis is unfavorable. *The treatment* consists in rest in bed, the administration of

opium or one of its alkaloids, and the application of hot or cold fomentations or turpentine stupes to the abdomen. If the affection is due to septic infection a saturated solution of magnesium sulphate should be given. If suppuration has occurred abdominal section should be performed with irrigation of the peritoneal cavity with normal salt solution (temperature 105°-110° F.) and the introduction of drainage.—(Gould's and Pyle's *Pocket Cyclopedia.*)

2. *Acute ovaritis* is usually secondary to salpingitis, as in gonorrhea and puerperal sepsis, but may occur as a complication of the eruptive fevers. The symptoms are pain and tenderness in the ovarian region, nausea, vomiting, rise of temperature, and rapid pulse. The *treatment* consists in rest in bed, hot vaginal douches, free purgation, hot fomentations over the lower abdomen, and removal of the diseased structures if the symptoms grow worse and suppuration ensues.

3.

ASCITES.	OVARIAN CYST.
1. Previous history of visceral disease.	1. No such history.
2. Enlargement comparatively sudden.	2. Gradual.
3. Face puffy; color waxy; early anemia.	3. Facies ovariana. Anemia absent, or later.
4. Patient on back, enlargement symmetrical; flat in front.	4. Asymmetrical until tumor is quite large; prominent in front.
5. Sitting up, abdomen bulges below.	5. No appreciable change.
6. Navel prominent and thinned.	6. Navel usually unchanged.
7. Fluctuation decidedly clear, diffuse throughout abdomen, but avoids highest parts in all positions, and always has a hydrostatic level.	7. Less clear; limited to cyst; not modified by change of position. No hydrostatic level.
8. Intestines float on top of fluid; hence percussion gives clear tympanitic note over the highest parts of abdominal cavity and dulness in lowest parts for all positions—*i.e.* areas of resonance and dullness change with position.	8. No change in areas of dulness and resonance with change of position. Dulness over cyst. Clear resonant note in all parts beyond cyst limits, *i.e.* in flanks and toward the diaphragm.
9. Vaginal touch detects fluctuation, bulging into vagina.	9. Vaginal fluctuation less clear or absent.
10. Uterus in prolapsed location, but position unchanged. Size and mobility unchanged.	10. Uterus displaced forward or backward, or laterally by pressure of cyst.
11. Hydragogues and diuretics temporarily remove the fluid.	11. Medicines have no effect.
12. Fluid light straw color and thin. Coagulates spontaneously.	12. Fluid light or dark and of varying consistency; albuminous, but does not coagulate spontaneously; may contain colloid matter.

—(From Dudley's *Gynecology.*)

4. MEMBRANOUS DYSMENORRHEA. *Symptoms:* Severe pain at the beginning of the menstrual period, which increases till the expulsion of a membrane, which may come away whole or in several pieces. After this the pain usually ceases until the next period. *Treatment:* Curettage, which may have to be repeated (perhaps more than once) before a cure is effected.

5. *Pelvic hematocele* is an accumulation of blood in the pelvis due to rupture of a blood-vessel; it is generally due to rupture of a tubal pregnancy, or to a tubal abortion. *Symptoms:* Pain which is sudden and severe, over abdomen and pelvis; nausea, cold perspiration, cold extremities, pulse rapid and weak, pinched features, and shock.

6. ABSCESS OF VALVO-VAGINAL GLAND. *Etiology:* Gonorrhea, or suppuration following cellulitis. *Symptoms:* The same as abscess anywhere else (redness, swelling, heat, pain, and sometimes fever and fluctuation). *Treatment:* Excision, or incision and drainage.

7. *Symptoms of salpingitis:* Pain or discomfort, made worse by pressure, examination, or defecation; or colicky pains over the tube; dysmenorrhea; increased menstrual flow; tubes are found to be dilated and swollen. *Varieties:* Hematosalpinx, when tubes are distended with blood; Pyosalpinx, when they contain pus; Hydrosalpinx, when they contain serous fluid or exudate.

8. *Urethral caruncle* is a small red fleshy growth generally situated on the posterior part of the meatus of the urethra. There are local pain and tenderness, which may be excessive; a burning sensation is experienced on urination; it may bleed. The proper treatment is to excise it or destroy it with the thermocautery.

9. RECTOVAGINAL FISTULA. *Symptoms:* Flatus and feces are passed by the vagina. Digital or speculum examination may show the fistula, and if milk is injected into the rectum, it will be noticed in the vagina. Vaginitis and vulvitis are present. *Treatment:* A plastic operation is necessary. The edges of the fistula are denuded and then approximated with sutures, the same as for vesicovaginal fistula.

10. GONORRHEAL VAGINITIS. *Symptoms:* Pain and burning in the vulva; pain and burning on micturition; dyspareunia; yellowish or greenish discharge, in which the gonococcus can be found; the vagina is hot, red, swollen, and tender. *Treatment:* Rest in bed, salines, mild unirritating diet, bathing of external genitals, copious vaginal douches of bichloride of mercury 1:2000 three or four times a day; later, the vagina may be swabbed daily with a solution of nitrate of silver 1 to 5 per cent., or with a solution of potassium permanganate 1 per cent. *Complications:* Cystitis, urethritis vulvitis, endometritis, salpingitis septic peritonitis, sterility, condylomata of vulva, abscess of Bartholin's glands.

SURGERY.

1. *Asepsis* means freedom from germs. *Antiseptics:* Heat, bichloride of mercury, carbolic acid, iodoform, formalin, formaldehyde, zinc chloride, albuminum acetate, potassium permanganate, hydrogen dioxide, creolin.

2. *Suture. Materials:* (1) Silkworm gut, used only on surfaces, from which it may subsequently be removed. (2) Silk, used in abdominal surgery, for suturing intestines and tying pedicles. (3) Catgut, used for buried sutures. (4) Kangaroo tendon, used for bone, and as an absorbable suture which will last a long time. (5) Silver wire, used for bone.

3. See Da Costa's "Surgery" (1908), pages 70 and 245.

4. *Paronychia:* Free and early incision, drainage, antiseptic dressings, tonics, and stimulants; the nail may or may not have to be removed. *Hordeolum:* Hot compresses, evacuate pus as soon as a yellow spot is seen, correct errors of refraction, look after general health. *Empyema:* Aspiration, drainage, irrigation, resection of ribs (Estlander's operation) or resection of chest wall (Schede's operation).

5. For diagnosis of *stones in the gall-bladder* see above, DIAGNOSIS, Question 3. *Stone in the urinary bladder* may be diagnosed by: Increased frequency of micturition; pain at end of urination, chiefly felt at the end of the penis or in the neck of the bladder; the urine may contain pus, mucous, or blood; a "click" can be obtained by using a searcher or sound; examination by the cystoscope may reveal the presence of the stone.

6. See Rose and Carless' "Surgery" (1908), pages 1044, 727, and 1115; or Da Costa's "Surgery" (1908), page 858.

7. See Rose and Carless' "Surgery" (1908), pages 975 and 980; or Da Costa's "Surgery" (1908), page 868.

8. See Rose and Carless' "Surgery" (1908), page 408; or Da Costa's "Surgery" (1908), page 1060. *Actinomycosis:* Treatment consists in free local excision; or incision with erosion and cauterization; slit up sinuses; drain pus cavities; give large doses of potassium iodide; tonics, stimulants, and best hygienic conditions are indicated.

9. *The surgical complications of typhoid fever* are: Gangrene; arthritis; abscesses and furuncles; otitis media; hemorrhage from stomach; intestinal perforation; infection of the gall-bladder; perforation of the gall-bladder; orchitis, epididymitis; parotitis; cerebral, laryngeal, thyroid, and thoracic troubles.

10. *Appendicostomy* consists in suturing the tip of the appendix to the abdominal wall, and then by opening the appendix at the tip access is gained to the cecum for the purpose of irrigating the large intestine. *Dactylitis* is inflammation of a finger or toe. *Osteomyelitis* is inflammation of the marrow of a bone (either with or without involvement of the bone). *Dubois' abscess* is an abscess of the thymus gland, found in congenital syphilis. *Hysterotrachelorrhaphy* is a plastic operation for the repair of a lacerated cervix uteri.

HYGIENE.

1. *Constituents of soil:* Silica, aluminum, lime, magnesium, phosphorus, sulphur, iron, manganese, chlorine, sodium, potassium, oxygen, nitrogen. *Physical properties of soil:* Porosity, permeability, capacity to receive water and

to contain water, heat, color, compactness, moisture, capacity for air and gases.

2. *Tilth* is the superficial layer of soil which is the result of the disintegration of rocks and the decay of animal and vegetable life; or that part of the soil which is moistened by the rain, warmed by the sun, permeated by the atmosphere, in which plants extend their roots and gather their soil food. *Marl* is a mixture of clay, sand, and amorphous calcium carbonate. *Loam* is a mixture of sand, clay, and humus. *Humus* is the entire product of vegetable decomposition in the various intermediate stages of the process. *Peat* is the result of the incomplete decay of vegetable matter under water, and is compact and fibrous. *Muck* is similar to peat, but is less compact, not fibrous, and when dry is easily reduced to powder. Humus will retain the greatest amount of water; and peat is probably the most inimical to pathogenic organisms.

3. The average depth to which the soil is self-purifying is about three feet. The dwellers on the soil retard the process by allowing organic filth and moisture to accumulate.

4. The sources and varieties of water have been classified thus:

- Wholesome:
  - 1. Spring water ..... } very palatable.
  - 2. Deep-well water... }
  - 3. Upland surface water ..... } moderately palatable.
- Suspicious:
  - 4. Stored rain water. } palatable.
  - 5. Surface water from cultivated land ..... }
- Dangerous:
  - 6. River water, to which sewage gains access ..... } palatable.
  - 7. Shallow-well water ..... }

5. A well may be polluted by a cesspool on a lower level, because it is not the location of the *outlet* of the well that determines the possibility of pollution; but rather the relative position of the cesspool and the *point where the water enters* the well.

In those cases in which the cesspool is on higher ground than the well, the latter may be protected by the geological formation of the ground, such as the presence of a ledge of rock.

6. Ordinary filter beds for the purification of water are tanks of varying size, shape, and construction; the walls may be vertical or sloping; upon the paved bottom are pipes to carry off the filtered water. Above these pipes are successive layers of coarse gravel, fine gravel, coarse sand, and at the top fine sand about four feet deep. Through these layers the water passes.

The fundamental principle of *Dibdin's bacteria beds* is based on "the idea that purification in a filter bed is not brought about wholly at the surface, but that the whole bulk of the filter is concerned therein, and experiments were made to determine the results of filling a bed and restraining the outflow for different periods, thus giving the organisms throughout the bed the same opportunity for action." (Harrington's *Hygiene.*)

The fundamental principle of *Cameron's septic tank* system is that "the sewage is first led into a tank from which air and light are excluded. Digestive changes take place in the sewage within this tank as the result of an anaërobic bacterial action, which is favored by the darkness, the absence of air, and the perfect stillness at which the sewage is maintained. Under these circumstances much of the solid matter is rendered soluble and dissolved."—(Notter and Firth's *Hygiene.*)

7. We inspire microorganisms; but, in health, we do not expire them.

8. For the support of human life, the air should contain nearly 21 per cent. of oxygen, about 78 per cent. of nitrogen, about 0.04 per cent. of carbon dioxide.

9. The result of inhaling carbon monoxide is that the carbon monoxide forms a very stable compound with the hemoglobin of the blood, and the result is that the hemoglobin cannot carry oxygen, and therefore asphyxiation occurs.

Less than 0.25 per cent. by volume in the air will cause poisoning; and but 1 per cent. is rapidly fatal to animal life.

10. "The occupations which are of particular hygienic interest embrace those which involve exposure to: Air vitiated by respiration; irritating and poisonous gases and fumes; irritating and poisonous dusts; infective matter in dust; offensive gases and vapors; extremes of heat; dampness; abnormal atmospheric pressure; constrained attitude; overexercise of parts of the body; sedentary life. Some occupations are conducted under such conditions that they may very properly be regarded as belonging to a number of these groups."—(Harrington's *Hygiene.*)

Medical Items.

Contagious Diseases, Weekly Statement.—Report of cases and deaths from contagious diseases reported to the Sanitary Bureau, Health Department, New York City, for the week of December 25, 1909:

	Cases	Deaths
Tuberculosis Pulmonalis	329	187
Diphtheria	347	44
Measles	487	13
Scarlet Fever	360	322
Smallpox	—	—
Varicella	186	—
Typhoid Fever	25	8
Whooping Cough	23	4
Cerebrospinal Meningitis	2	5
Malarial Fever	—	—
Totals	1,756	583

Hysterectomy by Anterior Separation.—T. de Martel advocates anterior separation of the tissues in hysterectomy as the best procedure. He clamps the round ligaments at a short distance from the uterus, separates and cuts the anterior layer of the peritoneum, perforates the posterior layer with a blunt instrument, through this opening clamps the urteine arteries, and then cuts off the cervix with curved scissors from left to right between two clamps. Traction on the body of the uterus is made while the index finger curves around the broad ligament and the adnexa form a pedicle and are separated. This method is easy, is applicable to all cases, no hemorrhage results, and there is no risk to the bladder. The removal of the uterus is a little slower than by other methods, but the benefits of the bloodless operation counterbalance this disadvantage.—*La Presse Médicale.*

Health Reports.—The following cases of and deaths from smallpox, yellow fever, cholera, and plague have been reported to the Surgeon-General, Public Health and Marine-Hospital Service, during the week ended December 24, 1909:

PROTECTIVE APPENDICITIS.*

By ROBERT T. MORRIS, A.M., M.D.,

NEW YORK.

PROFESSOR OF SURGERY IN THE NEW YORK POST-GRADUATE MEDICAL SCHOOL AND HOSPITAL.

THE time has arrived when we may conveniently classify four kinds of appendicitis.

1. Protective Appendicitis.—An irritative lesion, occurring in the course of normal involution of the appendix, and dependent upon irritation of nerve filaments which persist in the contracting hyperplastic connective tissue which has replaced other normal structures of the appendix.

2. Appendicitis with Intrinsic Infection.—An infective lesion which seems to be dependent upon any cause leading to rapid swelling of the inner coats of the appendix within the close outer sheath, with consequent compression anemia, and bacterial attack upon the tissues rendered temporarily vulnerable by such compression anemia.

3. Syncongestive Appendicitis.—An irritative lesion, due to the presence of serous infiltrates in the tissues of the appendix, and occurring synchronously with similar congestion of neighboring tissues. Such congestion is found with so-called lithemic swelling of lymphoid structures of the bowel; with obstruction of the lymph and blood circulation through certain diseases of vital organs, and with loose right kidney, which is said to cause obstruction by pressure upon the superior mesenteric vein.

4. Appendicitis with Extrinsic Infection.—An infective lesion, due to bacterial approach from other structures lying outside of the appendix, and progressing slowly enough to allow the appendix tissues to develop a good degree of leucocyte protection as a rule. This form of appendicitis is found with tuberculosis of the peritoneum or with infections proceeding from the uterine adnexa for instance.

We thus have appendicitis presenting itself in the form of two kinds of irritative lesion without infection, and two kinds of infective lesion.

The commonest lesion of the appendix vermiformis appears to be the irritative lesion which I formerly called fibroid degeneration of the appendix, but for which the term "protective appendicitis" is now proposed tentatively for the first time. The reason for this choice of nomenclature depends upon two facts: (1) Structures susceptible of acute infective processes are removed from the appendix by connective tissue replacement in the course of normal involution of the appendix, otherwise known as fibroid degeneration of the appendix. (2) I find nerve filaments persisting longer than most other structures in the appendix during the course of fibroid degeneration. These nerve filaments in the appendix are irritated by the contracting connective tissue, just as they are irritated in other contracting connective tissue in other parts of the body. The irritation of nerve filaments entrapped in the degenerating appendix, calls out a permanent local hyperleucocytosis which seems to protect such an appendix against bacterial attack.

Senn first called the attention of the profession to the lesion in question, in an article published in the *Journal of the American Medical Association* for March 24, 1894. He called the lesion "appendicitis obliterans," but did not separate it distinctly from the infective lesions. His nomenclature is not quite descriptive, because it leads to the conception that obliteration is due to the inflammation, whereas the contrary seems to be true, and the inflammation appears to be due to changes occurring in the course of an obliteration process.

FIG. 1.—An appendix which was quite normal in external appearance, but it felt harder than normal on palpation, and longitudinal section shows the inner coats to have been replaced by connective tissue, with total obliteration of the lumen. The patient had suffered from occasional attacks of pain in the appendix region, and from intestinal dyspepsia, both of which disappeared on removal of the appendix.

Ribbert in 1902 was the next author to give a position of importance to the lesion. On page 319 of his "Lehrbuch der speciellen Pathologie," he describes it as a normal involution of the appendix, and states his belief that the condition is provocative of infective processes. A study of the subject, with examination of what seems to be a sufficient number of specimens, leads me to the belief that we are to take at the present time, an exactly opposite view, and to note in practice if the irritative lesion called by Senn "appendicitis obliterans," by Ribbert "normal involution of the appendix" and formerly by me "fibroid degeneration of the appendix," is not actually protective against infective processes, and properly to be classified as "protective appendicitis."

*A paper presented at the International Medical Congress at Budapest, September 2, 1909. The author presented points in discussion without reading the paper, which will appear in present form in the published transactions of the congress.

The symptoms of protective appendicitis are of two separate and distinct kinds: (1) Local discomfort in the appendix region caused by the presence of sensory nerve filaments entrapped in contracting connective tissue. This discomfort persists for years. Sometimes there is acute local pain and tenderness, but not enough to send the patient to bed. In fact, these patients are particularly apt not to go to bed, on account of their general irritability. At other times there is merely a sensation of warmth in the appendix region, fluctuating in intensity from day to day—sometimes absent for short periods of time, and again attracting the attention of the patient for several days in succession. These patients are the ones who go the rounds of the profession asking whether they have appendicitis or not. Sometimes they are told that the discomfort is caused merely by the presence of gas in the bowel. At other times they are told that the condition is one of chronic appendicitis, and that operation should be performed for the removal of the appendix, on the ground that infection may suddenly supervene. We are to tell these patients, I think, that they are really protected against infective processes of the appendix, and that there is no need for removal of the appendix on the ground of impending danger. In some cases, symptoms of sensory and of functional disturbances seem to be altogether absent while the appendix is undergoing fibroid degeneration. (2) The second set of symptoms belonging to fibroid degeneration of the appendix has relation to sympathetic nerve filaments entrapped in contracting connective tissue. Sympathetic nerve filaments engaged in such tissue are irritated like the sensory nerves, but the demonstration appears to consist in a reflex irritation of the intimate ganglia of the bowel wall (Auerbach's plexuses and Meissner's plexuses). Disturbance of these plexuses appears to lead to chronic derangement of bowel function, and the patients form a considerable proportion of the class which is being treated for "chronic intestinal dyspepsia" with or without diagnosis referable to the appendix.

Fig. 2.—Two appendices in which all structures had practically been replaced by connective tissue, but enough nerve filaments had remained to cause persistent intestinal dyspepsia, for which the patients had received treatment by authorities without permanent result, until the appendices were removed. Both patients then became well.

There are three chief points for diagnosis of the condition of protective appendicitis, when they are observed in connection with the subjective history. (1) The most important point is hypersensitiveness on deep pressure at the site of the right group of lumbar ganglia, situated approximately an inch and a half to the right of the navel, and close to the lumbar vertebræ. If we make deep finger pressure at this point, finding a sensitiveness which is absent from the corresponding left side, we may look to the appendix as the original seat of irritation. Should there be hypersensitiveness at the sites of both right and left groups of lumbar ganglia, we may look to some pelvic structure instead of to the appendix, for the seat of original irritation, and this constitutes a point of considerable consequence in some cases in which we are not sure whether the appendix or some pelvic structure is at fault. (2) The second diagnostic feature of importance consists in a distention of the cecum and ascending colon to the hepatic flexure, with an undue amount or gas. The feature is not always present, but is found regularly enough to receive attention. It is my belief that the distention is not due to the presence of gas primarily, but that continued irritation of the motor nerves of the bowel in the region of the appendix leads eventually to relaxation of the muscularis and the formation of a receptacle in which gas readily collects in quantity. (3) Third in order for making a diagnosis, would come the testimony elicited by palpation, and the finding of an appendix that is harder to the feel than a normal appendix. Some very competent diagnosticians have expressed a doubt about our ability to palpate the appendix accurately, but it is my belief that palpation of the appendix can be accomplished pretty regularly after one has acquired a certain method of procedure.

The treatment for protective appendicitis must depend upon the particular case, rather than upon any rules. Many patients who obtain the mental relief of finding that they are not in danger, will get on very well under medical and hygienic treatment aimed at the intestinal indigestion. Other patients will have such a degree of persistent disturbance, that it is best to advise removal of the appendix.

Statistics of removal of appendices which are undergoing fibroid degeneration will probably be more favorable than statistics of any other form of appendicitis, for the reason that chronic irritation has called out chronic leucocyte protection of the vicinity. This one fact seems to make it desirable for us to classify cases of appendicitis for statistical purposes better than has been done in the past. Cases of protective appendicitis have usually gone into statistics along with the other three kinds, and it is now time for us to make a more scientific elaboration in

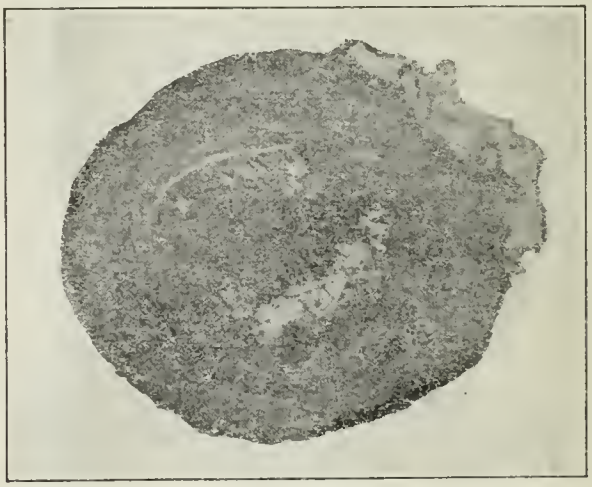

Fig. 3.—Cross-section of an appendix undergoing fibroid degeneration.

reports. The greatest danger from operation *per se* is probably in cases of syncongestive appendicitis, because resistance is apt to be lowered by the causes leading to serous infiltration. The next greatest danger from operation *per se* is perhaps when the perfectly normal appendix is removed, because we then open a point of infection in the midst of an unprepared field. On account of my interest in the subject of fibroid degeneration of the appendix, some of my assistants, for purposes of brevity, got to speaking of "Morris appendices," and this nomenclature at a distance began to be applied to normal appendices, but I have always been opposed to the idea of removing normal appendices, on the ground that it required a higher degree of skill and caution than I cared to exercise for the purpose. In cases of infective appendicitis, it is now possible for the surgeon to have a series of one hundred consecutive operations in unselected cases, including those with varying stages of suppuration, gangrene, and peritonitis, without having a single death, if he follows the principles of the fourth or physiological era in surgery.* In cases of appendicitis with extrinsic infection, we are apt to have a field protected by hyperleucocytosis. These facts seem to make it desirable to classify four types of appendicitis, and to make separate reports, particularly when dealing with fibroid degeneration of the appendix, *i.e.* the irritative lesion of protective appendicitis.

616 Madison Avenue.

WHAT MAY BE DONE TO IMPROVE THE HYGIENE OF THE CITY DWELLER.†

By S. ADOLPHUS KNOPF, M.D.,

NEW YORK.

PROFESSOR OF PHTHISIOTHERAPY AT THE NEW YORK POST-GRADUATE MEDICAL SCHOOL AND HOSPITAL; ASSOCIATE DIRECTOR OF THE CLINICS FOR PULMONARY DISEASES OF THE HEALTH DEPARTMENT; VISITING PHYSICIAN TO THE RIVERSIDE HOSPITAL-SANATORIUM FOR THE CONSUMPTIVE POOR OF THE CITY OF NEW YORK.

The subject which I have the honor to lay before you to-day is such a vast one that I know I will not be able to do it full justice. But I am presenting it before men who are all experts in sanitary science and who, by practical experience as health officers, will all have superior knowledge to one like myself, who is only an ordinary physician and whose practice has for years been virtually limited to only one disease. The object of my paper, therefore, is not so much to present to you my own views as to bring out discussions which I know, when they will be published, will be of great value and benefit to the health of that vast army of human beings dwelling in cities.

To choose a type, we will imagine an American city of medium size situated in a climatic region where the extremes of temperature are not too pronounced.

General and Outdoor Hygiene.—The general hygiene which concerns all classes alike (using the word "general hygiene" in contradistinction to home and private hygiene) is that part for which federal, state, or municipal health authorities, through their officers or agents, may be held responsible. The federal department of health must, as far as practicable, protect all communities from the importation of epidemic diseases, such as cholera, typhus, plague, smallpox, etc. While the state and local health authorities will, of course, cooperate with the federal health department for the suppression of all kinds of epidemic diseases, their function is, in addition, to protect the inhabitant from all endemic infections, such as tuberculosis, typhoid, scarlatina, measles, malaria, cerebrospinal meningitis, etc. The municipal authorities will also have under their supervision that vast prophylactic work which consists in the ample supply of pure water for drinking purposes, private and public baths, and an equally ample supply for perfect sewerage, for occasional flushing of streets, for possible conflagrations, and for more public toilet facilities properly and hygienically kept.

I do not think it is necessary for me to dwell on the inestimable value of an ample water supply or the necessity of its purity. I only wish to emphasize a few points regarding the necessity of hygienic drinking fountains in a large city. It is a deplorable and well-konwn fact that in many of our cities there are few, if any, hygienically kept drinking fountains where the water is cool enough in hot weather to be palatable. The well-known sanitary drinking fountains which make infection impossible, some of which are installed in the better modern schools but which should be installed in every school of the land, should also be a feature of the streets of any city which means to improve the hygiene of its dwellers.

I must not omit to say a word on the hygiene of the soda-water fountains which are such an important feature of our modern American cities. While the quality and character (freedom from narcotics and poisonous substances) of the flavors dispensed in soda water must necessarily be regulated by the food and drug inspection, a subject which we cannot discuss here in detail, I would suggest that a more thorough supervision of the methods of cleansing glasses and spoons after use should be inaugurated. Some reform is needed here, not only in the cheap stands which we see in the poorer quarters of the city where soda water is sold at one or two cents per glass, but also in some of the fashionable drug stores. The education of the consumer to the necessity for clean glasses and clean spoons would seem, however, as essential, if not more so, as any ordinances issued by the Board of Health.

Another point relating to public hygiene which is responsible for a great deal of discomfort is the lack of sufficient properly and hygienically kept public toilet facilities. This is not only productive of discomfort, often leading to habitual constipation, but our specialists in skin and genitourinary diseases tell us that actual disease results from this situation. I am also convinced that because of this lack of toilet facilities, many a man visits a saloon and takes a drink which he would not do did not the calls of nature make a demand on him to go somewhere. He feels a moral obligation to spend some money for the facilities offered and as a result takes a stimulant which he does not need and which in many instances proves injurious. Speaking of my own city, New York, I do not believe that there are outside of the parks more than a dozen public urinals and still fewer complete toilet facilities. Paris, which is certainly a beautiful city, has many thousands. With the exercise of a little taste they can be hidden behind shrubbery or neat screens. I venture to say that the installation of a

*See *Journal of the American Medical Association*, August 22, 1908, pages 644-648.

†Address delivered before the Section of Municipal Health Officers of the American Public Health Association, at the thirty-seventh annual meeting in Richmond, Va., October 21, 1909.

few hundred of such places would add to the comfort and health of many and would certainly reduce the useless, and in many instances harmful, imbibing of a good deal of liquor.

While I am, of course, an advocate of public baths and think them indispensable as long as we have tenements without a bath room for each family, the ideal would be that facilities for bathing in his own house should be offered to every citizen, rich and poor, old and young alike. The municipal creation of swimming tanks, not only in connection with schools, so that every child may learn to swim, but also for adults at reasonable prices, would certainly be a factor in enhancing the physical vigor and resistance to diseases of all city dwellers.

The value of the occasional flushing of streets and gutters and the sprinkling of the streets in hot and dusty weather is too well known to all sanitarians to need more than a mention here. Street sprinkling, however, should not depend upon private enterprise and street car lines should be compelled by the city authorities to sprinkle their tracks regularly whenever conditions demand that this should be done.

The next equally important matter is how to give to the city dweller the purest air, at least outside of his dwelling or work rooms. Could we rebuild all our cities we would probably lay them out differently, but even as they are something can be done. We know that the lower strata of the air in many city streets are very little stirred up by the purifying winds passing over them, and this is all the more the case when the city is built in the valley. In my recent book on Tuberculosis[1], I have ventured to make the following statement: The city of Chicago is one of the healthiest cities in the United States, and, while I gladly pay homage to the men at the head of its excellent sanitary supervision, there is no doubt in my mind that the wind to which the city is so much exposed is in no small degree responsible for its healthy condition.

My good friend, the Hon. Commissioner of Health of Chicago, Dr. W. A. Evans, who is to open the discussion of this paper, will probably reveal additional secrets to you and teach us what else he has done to make his city deserve that distinction. Nevertheless, in a country like the United States, where the founding of new cities is nothing unusual, the builders of the future should bear in mind that a city situated on high ground with wide streets will be a healthy city and relatively free from tuberculosis, pneumonia, grippe, and other infectious diseases of the respiratory organs.

With my lamented master, Geheimrath Professor Dettweiler, I claim that not too violent winds ("bewegte Luft") are rather beneficial than detrimental to tuberculous and similarly afflicted patients. In existing cities the widening of streets and the lowering of too high buildings will help the freer circulation of air and the admittance of sunlight will very materially improve the sanitary condition.

We are now coming to that often discussed subject of the smoke nuisance from which all our American cities, with but few exceptions, suffer to an almost humiliating degree. I trust you will not consider me partial when I point again to Chicago as a shining example.

How to do away wtih the smoke nuisance is, I confess, an exceedingly difficult problem. In many cities the use of soft coal cannot be forbidden by law because hard coal is not available, or available only at a very high price. It has been demonstrated that with care the skilled stoker can diminish the amount of smoke produced even by the lowest grade of coal. It would thus seem that in cities and towns where hard coal cannot be universally used on account of its price, the municipality should offer gratuitous instruction in the proper methods of burning soft coal to all those handling furnaces. Where this is done, city ordinances should be enacted and enforced with a view of minimizing the smoke nuisance.

From a very interesting report on smoke in relation to health, by Professor A. Jacobi of New York, the nestor of American physicians, who has taken a lifelong interest in the combat against tuberculosis, we learn that the latter disease, and also bronchitis and pneumonia have decreased since 1895 in London, Liverpool, and Manchester; that is to say, since the time an active anti-smoke crusade was started in those cities. One of the most important features of this crusade is a law limiting the time when black smoke may be expelled. Thus, in London and Manchester no factory chimney may expel black smoke for more than a minute every hour.

Strange as it may seem, in my humble labors for the tuberculous, whether I pleaded with municipalities or State governments, employers, or even philanthropists for the establishment of sanatoria, for the treatment or for a more efficient prophylaxis of tuberculosis, I have always been more successful whenever I could show by figures that it would be more economical to treat the patients at the right time and at the right place, and still more profitable from a financial point of view to the commonwealth, to prevent tuberculosis.

Regarding the smoke nuisance I venture to think that the same tactics might be used. Chief Engineer Wilson of the Geodetical Survey submitted proof that the damage which smoke inflicts every year in the United States amounts to more than $600,000,000 in the destruction of merchandise, the defacement of buildings, the tarnishing of metals, the injury of plant life, and the greatly increased labor and cost of housekeeping.

In commenting upon this report an interesting editorial in the Medical Examiner and General Practitioner, of June, 1909, very pointedly says: "But the money loss is not the worst. For careful medical statistics show that the breathing of coal smoke predisposes the lungs to tuberculosis, and even more violent lung troubles, such as pneumonia.

"And these facts lead to the conclusions of Engineer Wilson's notable report, that we are wasting of that most precious of resources, human life, 112,500 men, women, and children each year. If we appraise each life lost at $1,700, as is the practice of some European insurance companies, and the annual average earnings as $700, the economic gain to be obtained from preventing tuberculosis through smoky and murky atmosphere would be $270,000,000 in one year.

"And all this loss of life and health and efficiency and actual money is waste—sheer waste—a waste of dividends, as well as a waste of the bodies and souls of men. For every belch of black, carbon-laden smoke from a factory chimney is a proof of industrial incompetency. Imperfect combustion means smoke; perfect combustion not only means a better and more economical utilization of the coal, but also smokeless conditions."

It will not be very long before manufacturers and engineers will cease to object to the compulsory

avoidance of smoke on account of the acknowledged economic advantage due to a saving of coal. It would seem that from the recent literature I have been able to peruse, the smoke nuisance can be solved by the installation of a device known as the Bunson smokeless furnace, so named by its patentee, Mr. O. U. Bean, because it applies to steam boilers, the principle of the old Bunson burner for kerosene lamps. The company controlling the device has adopted a novel method of exploitation. They install the "Bunson" entirely at their own expense, protect their customers against fines for violation of the smoke ordinances of any city, however strict and rigidly enforced, and accept as remuneration an amount equal to the fuel saved their customers during a period of one year by reason of installation of the device.

Just as necessary as it is to prevent the pollution of streams by forbidding factory refuse or sewerage to be poured into them, so should we endeavor to prevent dangerous and obnoxious gases emanating from factories, and smoking and odoriferous automobiles from polluting our atmosphere.

In some European cities the emission of smoke and gasoline fumes from motor vehicles is under police supervision, and its restriction must be a great comfort to pedestrians and persons in other vehicles alike.

Garbage and ashes should be collected in covered wagons. There are a number of devices now in vogue in European cities so arranged that no ashes whatsoever are blown into the street during the emptying of the receptacles.

I have already spoken of the necessity of sprinkling the streets. Even sterile street dust, from the wear and tear of the pavement and from building material as well as horse dung, if inhaled in quantities is apt to irritate the delicate membrane of the lower respiratory tract and thus make it more vulnerable to the invasion of the tubercle bacillus. The custom which is in vogue in some European cities of having the horse dung removed as frequently as possible from public highways would seem a good practice to imitate. However, the advent of the automobile has in some small degree diminished this source of vegetable dust, but it has increased the amount of mineral and certainly more irritating dust on our public highways. The use of oil to allay the dust on roads much frequented by automobiles cannot be too highly recommended.

The cleaning of streets should preferably be done at night time. It can then be done more thoroughly, with less interference with the traffic and with less inconvenience to the people. It goes without saying that to sweep a street in a dry state and raise clouds of dust, should be considered a crime against the city dweller.

That the planting of trees in city streets should be encouraged from a sanitary as well as an esthetic point of view needs hardly be insisted upon. That a proper regulation of traffic and the speed of vehicles not only has a bearing on the safety and physical comfort of the city dweller and on his nervous system, but also an effect on the amount of irritating vegetable and mineral dust in the atmosphere, is self-evident. The careless or reckless automobilist, as well as the careless and reckless driver of any vehicle, is a distinct menace to any community.

But it is not only the dust and the danger at street crossings, it is also the useless, ear-piercing noises made by some of the reckless automobilists which have become a bane to many a city dweller's nervous system. To those who cannot see any harm in this practice I would wish to repeat the words which I recently read in some automobile magazine: "The less you use your 'Gabriel' siren or other ear-splitting device, the better for the comfort of those within and without the car. Use your hand horn with a gentleman's touch and reserve the atmosphere piercers for emergencies. They are valuable at times, but many people, especially sick ones, prefer other music."

Alas, the automobile is not the only cause of city noises. If the town is located near a navigable river, the citizen is sure to be treated day and night to the frequent blowing of whistles on the boats. That this kind of noise can be diminished without the perils to navigation being increased, has been sufficiently demonstrated in New York City through the efforts of the antinoise crusade inaugurated by some ladies under the leadership of Mrs. Rice. Numerable other useless noises, such as those caused by a flat or broken wheel on a street car, by street venders, carpet beating at all hours of the day, dogs barking and cats howling at night time, should be made subjects of antinoise crusaders in the city. The dog is not a useful nor a needed animal in the city, and even the utility of the average cat as a mouse or rat catcher can be questioned. A good mouse or rat trap will be more efficacious in the end, and the cat left at liberty at night should be considered a nuisance and promptly disposed of. The poor city dweller will then be spared the sleep-robbing cat concerts in his backyard. For any family to leave a housecat behind when they go away for their summer vacation is both cruelty to animals and to man. Beating carpets should be limited to certain hours in the forenoon and to certain days only* and I sincerely hope that the time may soon come when the price of pneumatic suction cleaning will be so reduced that the city authorities will be justified in making the beating of carpets prohibitory. No piano, graphophone, pianola, street organ, or street band should be allowed to be played before the hour of 8 A. M. and after 10 P. M.

The rigorous inspection of all the food and milk supply is a subject which concerns not only the city but also the dwellers in the smallest hamlet. We must, however, say a word on underground bakeries and underground kitchens, which are such frequent features of modern city life. The majority of them are absolutely insanitary, dangerous to the workers as well as to the consumers. These underground bakeries and underground kitchens should in reality not exist, but if they must exist they should be made as sanitary as possible and remain under sanitary supervision. As far back as 1899 I recommended in my textbook on Tuberculosis[2] the following precaution to prevent the handling of the bread by too many soiled hands. The moment the bread comes out of the oven, while it is still too hot to be handled, it should be placed with the aid of a shovel upon a piece of clean wrapping paper large enough to envelop the whole loaf. By twisting the two ends of the wrapper the bread is completely enclosed and protected from contact with unclean hands or garments until it reaches the consumer. City dwellers obliged to dine in restaurants are often served bread cut partially into slices. Any one desiring some bread takes the whole loaf in his hand and tears off a certain portion. It thus hap-

*In a number of European cities beating carpets is only permitted at certain hours on Fridays.

pens that the same bread is often handled by a number of individuals with more or less unclean hands. I consider this manner of serving bread neither appetizing nor hygienic; but to serve single rolls, done up in paper as just described, a practice in vogue in a number of the better restaurants of some of the larger American cities, is much cleaner, and is a method which should be insisted upon by the patrons of city restaurants.

Since the immortal discovery of Major Reed and his fellow workers has shown us that the mosquito is not only a nuisance and a pest, but that certain species are also distinct carriers of disease, such as malaria and yellow fever, it will add to the health and happiness of the city dweller to do away, as far as possible, with all the stagnant pools within or near a city. The fly, too, is now known as a common carrier of disease; municipal and individual efforts should combine in its extermination. The best exterminating agent for flies seems to be a weak solution of formaldehyde in water (two teaspoonfuls to the pint), to which should be added a little sugar. Flies are attracted to this mixture, which they drink; some die in the water, others will fall dead near the place. Houses should be constructed so that it would be impossible for them to become infected by such disease carrying and disease spreading pests as rats, mice, bedbugs, and other vermin.

In my epitome published in the program of this meeting, I have promised to venture my views on the question of alcohol in its bearing on the hygiene of the city dweller. It goes without saying that I will not attempt here to express an authoritative opinion based on experiments on the physiological effects of alcohol on man in health. I have never had an opportunity to do much original research along this line. My work in tuberculosis, however, caused me to come to the conclusion that alcohol used in excess predisposes to tuberculosis, and that the children of alcoholic parents contract tuberculosis more readily than children of temperate parents.

The belief that alcohol has a preventive or even a curative effect on the disease is, unfortunately, still prevalent among the masses. In my labors among the poor I have often sought to convince tuberculous patients of the folly of spending money for alcohol as a means to cure the disease. If they would spend the same amount of money for nutritious food (milk, meat, eggs), they themselves would probably have been cured much more readily and their families could have lived in greater comfort.

There are, of course, cases among consumptives and other sufferers where the judicious administration of alcohol is a help in nutrition in the diluted form, for example, of malt beer or wine with meals, and I would deeply regret if ever any law would be enacted to prevent the physician prescribing alcohol in the treatment of tuberculosis or any other disease. At times, particularly in the latter stages of chronic diseases, the administration of whiskey or wine as a stimulant may also be indicated.

One cannot study tuberculosis without at the same time becoming a student of sociology, and if you will permit me as a modest student of this most important science to express my opinion so far as it relates to the use of alcohol, I would wish to say that I believe the excessive use and abuse of alcohol to be responsible for more crime and disease than any other cause, and still I question the wisdom of absolute prohibition in our present state of civilization.

Could the Gothenburg system be carried out in the United States, I would certainly favor it as a means of decreasing intemperance, and consequently crime and disease. This system consists in the manufacture and sale of alcohol by the Government and giving the dispenser of alcohol a salary, so that no benefit shall accrue to him from the amount of alcohol he sells. It strictly prohibits the sale of liquor to the intoxicated, the habitual drunkard, and to minors. I am almost tempted to suggest this method to some of our prohibition States—it would probably tend more to decrease intemperance than prohibition laws do now, as they have worked in Maine, for example. However, with a heterogeneous population like ours, the same laws are, perhaps, not applicable to every State. Prohibition has decreased crime in the South among the negroes, while, if I am correctly informed, crime and arrests for intoxication are on the increase in Maine.

* * *

It is the same with individual states as it is with individual men and women. They have their idiosynerasies, peculiarities, and different constitutions. Some people cannot take a teaspoonful of liquor without feeling the intoxicating effect, others cannot drink the smallest quantity without a desire for more than is good for them being aroused. I have a dear friend of Irish extraction, one of the highest types of men, a doctor of philosophy. He is a total abstainer, for he assures me he feels certain that if he ever began to drink alcohol he would surely not be able to control himself and it would lead him to intemperance. It must be self-evident that these types of people with peculiar constitutions should religiously refrain from taking alcoholic drinks.

That a low type of saloon is injurious to any community every one will agree. It would seem that in most of our States it will be difficult to enact and enforce strict prohibition laws. To create by a higher license a higher type of saloon and diminish their numbers must surely have a good effect.

What in my humble opinion is injurious to the individual as well as to society, causing many a man to become intemperate, is, on the one hand, the American treating habit, and on the other, the habit of taking alcoholic drinks on an empty stomach and between mealtimes. For all this I have but one remedy—education. The treating habit, so far as liquor is concerned, must be abolished by teaching the young, by the practice and example of the adults, that it is wrong and should be considered un-American.

There are few men, and perhaps not one woman, in this country who would not be willing to do something toward the decrease of alcoholism and its concomitant social misery. If well-meaning men and women would unite in their efforts to suppress the treating habit by practice and example, and would pledge themselves never to partake of alcohol except in moderate quantities with their meals and in diluted form, I am convinced that a greater step toward temperance would be made than by any other means heretofore employed.

There are, of course, other causes which induce men to indulge in alcohol, or which predispose to alcoholism. I refer to bad cooking and bad house-

keeping, insanitary tenements, and bad hygienic conditions in general. A well-cooked meal, appetizingly served, in a well-kept and clean home, is perhaps one of the greatest inducements for the laboring man to shun the saloon. This fact was well brought out at the recent International Congress on Alcoholism in London (July, 1909). The growth of total abstinence in the British army was attributed by the surgeon-general to a very considerable degree to the improvements that have been made in the surroundings of the soldier, such as improved housing and food.

Healthful amusements and decent resorts where the laboring man on Sundays may take his family and partake of non-alcoholic drinks, would likewise add to the diminution of the alcohol evil.

Lastly, all statesmen, philanthropists and reformers, temperance advocates, and advocates of total abstinence should bear one thing in mind: while poverty and misery are often the result of alcoholism, poverty and misery are as often the cause. I am optimistic enough to think that with the continued betterment of the social condition of the laboring classes, with the diminution of poverty and want, intemperance and alcoholism as a social problem will also gradually disappear.

Indoor hygiene concerns all classes. In a recent paper read before the American Academy of Medicine on the Relation of the Medical Profession to the Housing Problem, I stated that all civilized men spent one-third of their lives indoors for sleep, and of all workers in the various fields of activity by far the greater number have indoor occupations. According to the United States Census of 1900, there were 29,073,233 persons over ten years of age engaged in earning their livelihood in some one of 303 specified occupations, out of which only 46 could be distinctly called outdoor occupations. The total number engaged in these latter were 12,058,671. The number engaged in the 257 indoor occupations would thus be 17,014,562. If we add to this the time all classes of people spend indoors for amusement, instruction, or worship, well may we say that the greater part of the people of the United States virtually spend their lives indoors.

This classification, of course, does not give an idea of the hours many of us spend indoors by traveling in railroad cars, street cars, etc., and street car hygiene certainly concerns the city dweller. This hygiene can be improved, on the one hand, by the railway car companies, on the other hand, by the personal effort of the citizen himself. The cars should be kept clean by the companies; they should be constructed and managed so as to make travel not a discomfort. If straps for holding on must be provided because there are not always enough seats, these straps should have a celluloid covering which should be washed daily and will thus not constitute a constant harbor of pathogenic microorganisms. Tht regulation of proper heating and ventilation of cars should be carried out by the conductors who should have definite instructions. These regulations should be for the comfort and health of the passengers.

Where there are subways as we have in New York and where natural ventilation seems difficult, these underground tubes should be supplied with some ozone-generating apparatus. In view of the fact that all the traction is by electricity, this installation could be made with relatively little expense and much of the discomfort and even illness often experienced by the city dweller obliged to use the subway could be done away with. However, I have been told that if, in addition to this, sheet-iron partitions were placed in the center of the subway to divide the tracks, much of the polluted and dangerous atmosphere would find a way of escape by being pushed out by the moving trains wherever an opening exists. Other recommendations are to force out the bad air and force in the pure air by compression, the pure air being obtained from tall shafts on the outside.

While personally, of course, I approve most highly of antispitting signs in our street cars, they seem to me insufficient in their purpose if they do not include also, in some measure, some phrase to prevent droplet infection. I have seen people in crowded street cars cough in others' faces and I have been the recipient of droplets from coughing people myself. We know that these droplets, when coming from the consumptive, often contain the tubercle bacilli. We know, also, that they may contain the pneumococcus and the grippe bacillus, and I am convinced that this droplet infection in street cars is at times of grippe epidemics one of the fruitful sources of the spread of the disease. Thus, it would seem to me that a little warning which might read like this: "Hold your hand or handkerchief before your mouth when you cough," might be profitably added to the antispitting ordinances. Those of us who are willing to observe will, however, grant me that education, or better yet, the awakening of the people to their duties to help prevent preventable diseases, is indispensable if we desire to improve the hygiene of the city dweller.

The managers and superintendents of places of worship, amusements, instruction, and recreation, such as churches, theaters, music halls, courtrooms, postoffices, railway and police stations, lodging houses, etc., should be compelled to keep these places hygienically clean and provide at least a reasonably good ventilation. The individual communion cup[3], or at least the sanitary communion cup[4], should replace the ordinary common communion cup wherever such ceremonies are performed. The kissing of articles of adoration, such as crucifixes and images, should only be permitttd after thorough cleansing of the object.

To provide good factory, workshop, department store, and office hygiene, and to install safety devices for the protection of the employees, should be the duty of every employer. The individual city dweller has little control over it. The employer can be shown that it would be to his own interest and even to his financial advantage if he would look after the health and well-being of his employees. Let me relate only one instance. I know of a telephone exchange connected with a large concern where numerous young women are employed, some of whom had contracted tuberculosis. Absences for indisposition and ill health, amounting often to several days, were frequent. Seeing the service crippled, the manager demanded from the head of the firm that more space should be given to his department, a restroom and better washrooms provided. From his personal funds the manager gave to each girl a warm sweater and advised them to dress particularly warmly, for henceforth he was determined to keep the windows open, no matter how cold it might be. The result was, no more tuberculosis, no more absences for illness or indisposition, and better and more efficient service. If employers will bear such experiments in mind and adopt them as far as practicable in their own in-

stitutions, I am convinced that they will be the financial gainers in the end and their employees will be made happier and healthier.

Home and Private Hygiene.—There is no doubt in my mind that if all city dwellers could spend a little more, and some a good deal more, time in the open air, they would be in a better physical condition. This holds good for old and young. There should be more outdoor recreation places, more parks, more gardens, more outdoor restaurants, etc. In New York, for example, there are thousands of acres of roofs, which, could they be transformed into roof-gardens, playgrounds for children, or resting places for mothers, on hot summer evenings, incalculable comfort would be bestowed upon that large class of city dwellers obliged to remain in town during the hot season. The average roof can be transformed into a roof garden with relatively little expense.

The indoor hygiene in the homes of the poor is, perhaps, the most important portion of our subject and also the most difficult one. The first thing we have to deal with is the problem of congestion, and while, of course, the indoor arrangement and hygiene of the city dweller is of vast importance to poor and rich alike, let us be frank and admit that the air which the masses get in the crowded tenement districts is not pure enough to make them strong, vigorous, and resistant to disease even if they keep their windows open. Not until we insist upon lower buildings and wider streets, particularly in our tenement house districts, whereby more sunlight can enter their habitations; not until our old tenement houses, and particularly our murderous lung-blocks, are replaced by model tenement houses; not until we have interspaced these model tenement houses by multiple parks and playgrounds; not until this fearful congestion, which is now the curse of our civilization, has been done away with; not until the suburbs of our large cities are utilized for individual homes of the masses; not until our traffic facilities will enable the laborer to travel in comfort and with rapidity to his sanitary home; not until we have given him the opportunity to live modestly but decently in a home somewhat closer to nature than the dark, dreary tenement houses of our overcrowded cities, will we be able to speak of an improvement of the hygiene of this class of city dwellers.

However, it must be borne in mind that the rental for such sanitary homes for the laborers should not be so high that he and his family must deprive or stint themselves of other necessities of life. When one considers the present unusual high prices of articles of food and clothing, the rental the average laborer is able to pay dare not exceed one-fifth of his income.

The indoor arrangement of the homes of the poor, of those of moderate means, and even of the rich, is in many instances deplorable. The best ventilated and sunniest room is usually reserved for the parlor, relatively rarely occupied, and the children are put in the darkest, smallest, least ventilated bedroom, where the sun hardly ever enters.

The methods of heating city houses is of the greatest importance. The best system for those who can afford it, is that of direct heating where a large quantity of moderately warmed air is brought into the room, say over steam, or better yet, hot water coils. Hot-air furnace installation is the cheapest, and is, therefore, the best that can be used for the poor. Ordinarily, the poor heat with stoves combine the objectionable features of systems that heat the air contained in the rooms without changing it, with the objections to systems that burn the air; moreover, presenting great danger of allowing gas to escape. Especially is carbon monoxide given off through the pores of the iron when these stoves become red hot. The usual systems adopted in homes on account of the balancing between expense, convenience, and hygienic reasons are steam heat, or better but more expensive, hot water, with radiators placed directly in the rooms. There are so many cracks in the ordinary house that considerable ventilation is assured. Moreover, most houses have fireplaces which promote some ventilation even if there is no fire burning.

Many of our American houses, however, are too tightly built, are kept at too high temperature and the air is not changed often enough. Besides all this, the air we breathe in many of our overheated houses is altogether too dry to be sanitary. Experience has proven that we can be perfectly comfortable in a temperature of 65° F. and even a little lower, provided that the relative percentage of moisture is 60. If this moisture falls to 30 or 20 per cent., then the dry throat, dry nose, and dry skin are in evidence. The explanation is simple. The dry air absorbs the moisture from the body and causes discomfort. The drying of mucous membranes in this way lays them open to the invasion of the organisms causing colds, grippe, pneumonia, and tuberculosis. Thus, the excessively dry atmosphere of many city and country homes in winter often gives rise to nasal catarrh—a condition which everybody, but especially those suffering from pulmonary diseases or prone to them, should be anxious to avoid.

Besides keeping the water-pan in the furnace constantly filled, there should be in the sitting-room and sleeping-rooms some evaporating arrangement, such as the one known as a humidifier, which I have illustrated in several of my previous writings.[5] More simple evaporating devices, however, may be arranged to render the atmosphere sufficiently moist. To determine the proper humidity, the direct reading hair hygrometer answers all practical purposes.

The best method of cleaning our rooms and furniture is, of course, by the pneumatic suction process already mentioned, but for those who cannot yet afford this luxury it might be well to remember Prudden's excellent simple rules, which read as follows:

To prevent making a great dust in sweeping, use moist sawdust on bare floors. When the room is carpeted, moisten a newspaper and tear it into small scraps and scatter these over the carpet when you begin sweeping. As you sweep, brush the papers along with the broom and they will catch most of the dust and hold it fast, just as the sawdust does on the bare floors. Do not have either the paper or the sawdust dripping wet, only moist

It goes without saying that the feather duster should be banished from all houses and replaced by the cloth with which dust should be wiped off.

The city dweller should, of course, remember to sleep always with his windows entirely, or at least partially open, and bear in mind that night air in cities is not only just as pure but often purer than day air because there is less traffic and commotion in the street at night time.

The internal equipment of the living rooms of the city dweller should be with a view to preventing accumulation of dust and concomitant danger of

spreading disease of the respiratory organs. Thus, fixed carpets, cloth curtains, and worse yet, cloth tapestry, should be abolished. The plush or velvet covered chairs are likewise to be considered dust collectors, and smooth cloth, or, better yet, leather or imitation leather covering is far superior from a hygienic point of view. In building new houses or remodeling old ones, to round off corners in our apartments will doubtlessly add to the facility of keeping our dwelling rooms relatively free from the accumulation of dust.

The least attention in the arrangement of our living rooms is usually given to the toilet room. The water-closet in a dark unventilated room is in itself a menace to health. It becomes even a greater menace when it is a bad water-closet. There are any number of water-closets where the flushing stream only cleanses a part of it. Think of the danger if such condition exists in a home where there is a typhoid fever patient. Unfortunately, this type of water-closets is also found in some of the better-class hotels, in railway stations, public comfort stations, and railroad cars. I wonder if typhoid fever epidemics may not have their source in this deficiency, particularly when we bear in mind that flies, the carriers of so many infectious diseases, are often plentiful in such places.

One general defect in water-closets I have noticed as much in elegant homes as elsewhere, is the height of the seat. For any except very tall men this causes a wrong position to be assumed and it is impossible to exert the necessary abdominal pressure for a free evacuation of the bowels. With short persons, men, women, or children, the feet often dangle in the air and constipation becomes a chronic condition owing to the incomplete emptying of the bowels.

To avoid the possible infection from venereal or skin diseases in using any of the public water-closets, I would urge the practice of protecting the seat each time the toilet is used with a new clean layer of paper with a circular opening. This practice is in vogue in some of the European public comfort stations.

The chronically ill of any large city, which are mainly composed of the tuberculous and the insane, should be housed as far as possible in the outlying districts of the city, and the tuberculous poor for whom the city must care should be divided according to the stage of the disease, and in making this provision Pryor's maxim should be followed; that is to say, treat the patient at the right time, in the right place and in the proper way when he is still curable, and not at the wrong place, at the wrong time, and in the wrong way when all hope must be abandoned.

The dark, dreary, badly ventilated tenement home is no place for the consumptive. He not only will not get well there, but if he remains there he will constitute a constant menace to his family and other city dwellers.

What has been said of the care of the tuberculous can also be said of the insane. They, too, when timely treated in proper surroundings, will often get well, while, when in the advanced stages of the disease, chance for recovery is rare.

To speak in detail of the acutely ill among city dwellers would mean a discussion far beyond the scope of this paper. A proper hospital system with proper ambulance facilities, and hospitals built according to the latest conception, must be the feature of every modern city which means to do its duty towards its inhabitants. However, for the acutely ill there is one provision missing in most of our American cities of which I desire to say a few words in detail. I refer to convalescent homes. Our surgical and medical wards are usually filled with acute sufferers, because of lack of room they must often be dismissed before the patient has completely recovered from the actual operation or from his acute disease, much less from the debilitating condition which results from the operation. The misery and suffering which results to many an honest city dweller in moderate or poor circumstances, because of being discharged from the hospital as convalescent but not as cured, and unable to resume his former occupation, is pathetic. No city hospital system is complete without a home for the convalescent from acute surgical or medical illness.

In a truly modern city there should be no paupers. Those who honestly seek work should be provided with work and be sufficiently paid. The pauper able to work and who does not wish to work should be made to work. A splendid move in the right direction has recently been inaugurated in the City of New York under the name of National Employment Exchange, 14 State street. No charge is made to those who obtain work there. It is a purely philanthropic institution, inaugurated and in charge of Messrs. Robert W. DeForest, Edward T. Devine, Paul U. Kellogg, and Jacob H. Schiff.

For the morally ill, for such I call those who are usually stigmatized as criminals, I plead for humane prisons and humane prison management. The detention prisons, through which not infrequently an innocent person has to pass, should not be so unhygienically managed as to expose anyone to the contraction of disease. For the inmates of all our penal institutions I plead for better prison hygiene, for better ventilation of workshops and cells, proper food and proper occupation. It is a sad comment on our civilization and on the management of prisons that the mortality from tuberculosis in the average prison is still three times higher within its walls than without. No matter how gravely morally ill the inmate may be, we have no right to add to his sentence of imprisonment the additional sentence of death from tuberculosis.

Each city dweller should realize his responsibility towards the others and do his part to improve existing conditions. First of all, in order that the city dweller's health may be protected not only against insidious disease, but also against bodily injury, traffic regulations should, as far as possible, be perfect; speeding with any kind of vehicle, except for ambulance calls and fire, should be prohibited by reason as well as law. There are far too many deaths and injuries resulting from the speed mania. All traffic regulations and all safety devices will, however, be of little avail if the conscience of those who own and drive automobiles and other fast-going vehicles is not awakened to the fearful responsibility they assume by careless and unscrupulously fast driving. Unavoidable accidents will happen, but many automobile accidents could be avoided, particularly in cities, if the chauffeur himself would be more considerate for the safety and life of pedestrians. For the automobilist to injure an individual, no matter whose the fault may be, and then leave the unfortunate wounded person to his fate and try to escape his responsibility by speeding away, should be considered an abominable crime with which the law should deal most severely. Lastly, to diminish the frequent accidents from

which American travelers and railway employees suffer so much, safety devices on all cars and trains should be obligatory.

When one compares the frequency of fires and the loss thereby of property and life in American cities with those of Europe, one cannot help being sadly impressed by the fact that our precautions against fire must be sadly deficient. While our American fire-fighters are certainly superior in alertness and efficiency to any of their European comrades, our municipal laws and individual precautions against the outbreak for fires are decidedly inferior. In the larger European cities the installation of every fuel-consuming device, for the factory boiler to the smallest stove in the smallest tenement home, is subject to regulations and supervisions which lessen the accidents by fire and fatalities connected therewith by more than one-third as compared with those in the United States. To the perils arising from the lack of supervision of furnaces, stoves, etc., has been added in recent years a new danger by allowing the remnants of gasoline tanks to flow into our sewers, the result of which, as is well known now, is many sewer explosions and concomitant accidents. In our age where gasoline is an almost indispensable product, its handling should be regulated by the enforcement of the strictest laws under the supervision of the fire or health department.

As far as family and personal hygiene is concerned, we must look for our salvation to public education through schools, the right kind of lectures, popular literature, and above all to the teachings of medical men and women. The city dweller should know how to dress. When one has seen in hospital work in the city of New York an individual brought in suffering from sunstroke and on being undressed he was found to have three flannel shirts under his waistcoat and coat, one realizes the need of education in this respect. The ignorant citizen should be taught and the knowing permitted to dress according to weather and season. If I am rightly informed, our higher postal authorities do not allow the letter carriers to go without a coat even in the hottest weather. Last summer, on one of the hottest days of the hot season I saw a gentleman enter a fashionable restaurant in white negligee shirt and belt looking neatly dressed, and one would have thought properly for the season. He was refused the cooling drink he asked for because he had no coat on. It was in the evening. There were ladies present with no hats, in cool decolleté summer dresses, decolleté in front and behind, with no sleeves, some with shirt waists of the thinnest material, some of material largely fenestrated—all were admitted and served, but the man had to go thirsty until he could cover—not his nakedness, but his nice, clean white shirt which covered his arms to his wrists and his neck to his ears. It is an absurd custom that men should not be allowed to dress as coolly as women. Except in cold weather, I consider the stiff linen dress shirt uncomfortable and unhygienic and the stiff tight and high collar for man and woman unhygienic all the time. The turned-down or soft collar should be made more universal for ordinary use. The negligee shirt is far superior to the others. The derby hat, such a prominent feature of city life, which, when worn a long time, constricts the circulation of the head and is doubtlessly the cause of much baldness, should be replaced by the more hygienic soft felt hat. To wear the hat indoors, which is also the habit of so many business and laboring men, is a habit which cannot too severely be condemned from a hygienic point of view.

Of dress reform in women much has been written and it has been still more talked about. In a recent conversation with a very progressive young lady physician, who, to my amazement, I thought to be laced more tightly than was good for her, I ventured to drop a word sounding somewhat like "bad example." The reply was like that of any other woman that she wasn't really tightly laced, but she also volunteered the information that it was we men who demanded what we considered graceful figure, small waists, etc. Be that as it may, it seems to me that as long as women will submit to the dictates of fashion, whether reasonable or not, we men have little to say about it. I perceived that our tastes were not consulted apropos of large hats, Empire dresses, nor of the fashion of dresses and waists being fastened in the back by multiple buttons and hooks.

Trailing skirts are now mostly out of fashion for the street, and I hope these garments, which so often do the scavenger's dirty work, will never come in fashion again. These skirts, trailed too often in tuberculous dust, carried the germs into the playrooms of children and caused many a little one, without any hereditary predisposition or other exposure to infection, mysteriously to become tuberculous. Education in dress and home hygiene should form a part of the curriculum in schools to the future city dweller—man or woman—and for the latter practical cooking lessons should form a feature.

The social ill and the collateral unfortunate condition manifesting itself in the prevalence of venereal diseases and its sequellæ (invalidism, blindness, sterility, etc.) is, indeed, a feature which must be entered into in the discussion of our subject. But I must be brief and can only refer here to what I have said before in a paper entitled "Some Thoughts on the Etiology, Prophylaxis and Treatment of the Social Ill."[6]

The improvement of the hygiene of the homes of the poor to which I have already alluded, the suppression of child-labor, the betterment of monetary compensation for the young woman who has to go to work in shop or factory, the education of boys and girls and the public at large as to the meaning of sexual relations, and the prevention of venereal diseases, healthful amusements, evening dispensaries and free treatment for those afflicted with venereal diseases and unable to pay, hospital facilities for the treatment of more serious cases, repression of the social ill, and, last but not least, a home or a house which may serve as a refuge for the poor, unfortunate sister who is tired of the life she is leading, an opportunity for her to forget and begin a new life—these are the remedies I suggest. Efforts in the direction of providing such homes and giving the women an opportunity for work and employment in other spheres is one of the most efficacious ways of helping to solve the problem of the social ill. This has been amply demonstrated by the recent report of Miss Maude E. Minor, one of the New York City Probation Officers, through whose untiring effort such a home, known as the "Waverley House," was established two years ago. Of 300 women who passed through this home either by self-commitment or on probation granted by the court, 119 had changed their mode of life, had become happy, honorable, and useful members of society and are in constant communication with Miss

Minor. Every letter from them expresses their gratitude for having been enabled to leave a life in which they were so thoroughly unhappy. A place of refuge for those unfortunate women in many instances means freeing them from the men who live on their shame and are so often responsible for their enslavement.

Before coming to the end of my paper I feel in duty bound to say a word on the hygiene of the nervous system and the brain of the city dweller. To define the physical and nervous condition of the dweller in the large city of New York, my friend, Dr. John H. Gardiner, has created the word "Newyorkitis." According to him Newyorkitis is the cause of the artificial life which so large a percentage of New Yorkers are leading or are obliged to lead and which has its effect in a peculiar condition of the mind, body, and soul of the individual.

I believe I have said all that I could possibly say in this paper concerning the bodily welfare of the city dweller, and I will only dwell for a few moments on the alarming increase of all kinds of nervous diseases and insanity. What can we physicians do to stem this tide and bring about a more rational and more sane method of life so as no longer to overcrowd our insane asylums and sanitaria for nervous diseases? What our brethren, the ministers and pastors of all the different creeds, seem to have been unable to do in most instances, we must now try to accomplish. We must become the physicians of the souls of men, we must guide our patients in the right direction, particularly those who are threatened with diseases of the mind because of constant worry, often useless anxiety, and still more often unnecessary hunt after the almighty dollar. Then there is that large class of patients which might be called pleasure hunters. They as well as the hunters after wealth should be impressed with the need of a better equilibrium in their conduct, more hours of sleep and healthful recreation, and some ideal, some noble aim to live for. The lack of a sufficient amount of rest and sleep is, perhaps, as responsible for as much nervous and mental affliction as anything else. There should also be more time at the proper time devoted to our meals. The quick lunch and the midnight heavy supper are alike injurious to our physical and mental condition. In other words, we must live a simpler life. This, however, does not mean to abandon the comforts of modern civilization, to ignore the blessings of modern science, of music, art, and literature. It only means to live less artificially, more in accordance with physiological, *i.e.* natural laws and obey the lessons modern science and preventive medicine have taught us. This applies to men and women alike, but to the latter I feel that I must give an additional word of warning. Instead of giving their adherence to all sorts of fads, some of which deny the existence of disease and proclaim the uselessness of preventive medicine, hygiene and the laws of cleanliness, which are the laws of God, the American mother should combat such dangerous doctrine by word of mouth and pen, and above all, by example. If she leads a more simple life, she will no longer be "nervous," or neurasthenic, and consequently will not have to resort to the patent medicines, headache powders, and nerve tonics advertised in the daily papers and not infrequently even in religious periodicals.

It is the physician, and particularly the family physician, who, if he rises to his opportunities, can become the greatest benefactor of our age. If he can inspire his patients to lead a simpler, a more quiet, less materialistic, and better balanced life; if he can teach them to be satisfied and contented with less of the world's goods than others possess; if he can convince them that seeking for the world's possessions is only laudable when it causes no detriment to their own physical and moral being and that of their fellowmen; and that the healthy mind in the healthy body of the contented man or woman is far more precious than the material riches of all the world; if, as my esteemed friend, the Rev. John Haynes Holmes of the Unitarian Church of the Messiah, New York City, puts it, the physician can convince the business man that business should be contributory toward the happiness of the people, that business is for man and not man for business; then, indeed, will he be the physician not only of the body, but also of the soul and will see his reward in the increased happiness of all and a healthier, more moral, and saner state of society at large.

I have promised to conclude my paper by the discussion of the hygiene of the child of to-day—the citizen of to-morrow. Let me begin by saying that to have a vigorous race we must have more breast-fed and fewer bottle-fed babies, we must not allow the women, the future mothers, to work in factory and workshop until the day before confinement, nor resume work after a week at the maternity hospital or childbed at home. Let us provide maternity sanatoria for these future mothers where they can rest long enough before and rest long enough after confinement. Let us instruct the future mothers in the care and raising of children and there will be fewer epidemics of measles, scarlet fever, infant diarrhea, and tuberculosis.

School hygiene is a subject on which one can write a book, and a pretty voluminous one at that, and I only want to venture to suggest a few points in relation to it. The average child should not be sent to school before he is 8 years of age. More play, and more outdoor play, should be the privilege of the child at all ages, but particularly under the age of 8. Every city should have an abundance of playgrounds and every school should have its outdoor playground adjoining the school or have it built on the roof if there is no other room. The curriculum should be regulated so as not to develop the brain of the child to the detriment of his nervous system and proper physical growth, nor to make physical or mental wrecks of our schoolteachers. Botanical and geographical excursions, outdoor singing and recitation (weather permitting), should be a feature of the curriculum of all classes. During recess, respiratory exercises in the open air or at the open window should be practiced for a few minutes. Ventilation in the schoolroom should at all times be the best which can possibly be obtained. Proper paper, proper length of lines in school books, proper interspaces, in short, everything appertaining to safeguarding the eyesight of the school children should be considered of paramount importance in school hygiene. May I say incidentally here that a movement for larger type in our daily papers, such as has been inaugurated by the New York *Herald*, should be emulated in all American cities. Open-air schools for the tuberculous or the predisposed child should be a feature of every modern school.

I have already mentioned child-labor as often

predestining the young girl to become a victim to the social ill. Child-labor also predisposes to tuberculosis, weakens the nervous system in its resistance to the temptation of alcohol and other vices in both sexes. However, it is not only child-labor in the factory which we must try to suppress, the child-labor at home is often quite as serious. Sometimes a cruel, sometimes a thoughtless and sometimes a poor parent has crippled the child for life by forcing it to slave at home in one type of labor or another. Such a child will make a poor citizen if it ever grows up to man or womanhood.

I know I will meet with opposition in what I have to say on the question of race suicide. In the sense of the interpretation of our distinguished Ex-President Roosevelt there exists, I believe, no race suicide in the homes of the poor. If anyone doubts this statement, I refer him to statistics, but a visit to anyone of the streets in the tenement house districts in New York or any other large American city will convince him of the truth of my statement. Nevertheless, there is race suicide in those regions, inasmuch as many of the children of the families of 5, 6, 7, 8, 9 and 10 either die young or fill the schools with anemic, undeveloped, physically, and often mentally crippled pupils who, if they live, in later years frequently become burdens to the community by reason of their invalidism.

I have for years taken careful statistics as to the number of children in the family from which a consumptive came. This has shown that in large families usually the latter born were the ones who contracted tuberculosis. It was with the constant increase of the family that the struggle for life on part of the parents increased, less care was bestowed and less food and poorer food had to be given to the latter born than to the first born. This inquiry into the family history has also very frequently revealed to me the fact that those large families never remain large families. Many of the children die before they reach adult life. This seems to me a costly race suicide. The remedy is again education and enlightenment. After all, in the make-up of a nation quality is more important than quantity.

To summarize: it is by thorough training of ourselves as physicians and sanitarians, the awakening of the statesman and philanthropist to their duties regarding issues of public health and public welfare, education of employers and employees, of the man and the woman of all classes of society, in general and personal hygiene; hygienic education of the child at school, and the practical application of the combined knowledge and experience gained in modern sociology, pedagogy, eugenics, and medicine that we may hope to make of the child of to-day the citizen of to-morrow, the ideal man and woman, strong, healthy, happy, vigorous, noble, and even beautiful to behold.

DEATH IN EPILEPSY.

By J. F. MUNSON, M.D.,

SONYEA, N. Y.

LABORATORY OF THE CRAIG COLONY FOR EPILEPTICS.

It is the common idea that epilepsy is a disease carrying with it but small danger to life, that while it makes its victim a dependent, an outcast, he may live on fairly indefinitely. Our experience at the Colony is in direct contradiction to this idea—our experience is that the disease carries with it very grave dangers, the span of life is shortened, and there is a special liability to certain diseases and to traumas.

The material from which this paper is constructed is drawn from the records of, 2,818 admissions to the Colony, representing 2,732 individuals. Before discussing the deaths, it may be of interest to show the ages at which our cases were admitted and the age at which the disease began. (Chart 1.)

In this chart, each space to the right represents a year and each small space vertically represents a case. The solid line represents the ages at admission and the broken one, the ages at onset. It will be seen that the very early years of life have but few representatives among our patients: half our cases were received at from eleven to twenty-five years, inclusive, and the greatest numbr at any one age was at seventeen. It may be remarked that the sexes were divided in the proportion of six men to four women. The onset line shows graphically the well-known facts in the etiology of the disease, that infancy and puberty are the most dangerous periods for the appearance of this disease. The latter part of both curves is of interest in that there is a steady fall from the crests to the oldest case shown. There is no rise corresponding to the later years of life, and it seems that to this fact may be attached considerable significance, for it shows that among our patients those causes which are active in later life, arterial change, senility, syphilitic conditions, and the menopause, have but little part.

Of the 2,732 individuals above mentioned, 582 have died at the Colony. Many have been discharged, and nothing is known of their subsequent history. The proportion of males and females dying is practically the proportion admitted, though the males are very slightly in excess.

For the statistical analysis of these cases, attention is called to the remaining figures herewith presented. Chart 2 shows the ages at which death occurred, and it will be seen that this is somewhat similar in shape to the curve of the ages of admission, except that it is pushed to the right somewhat. The maximum number of deaths at any one age was at nineteen, while 50 per cent. of the deaths lie between the ages of fifteen and twenty-nine years, inclusive. The arithmetical mean is 30.08 years. This certainly indicates a lessened expectation of life.

Chart 3 shows that the onset of the disease was in these cases of the same character as in the entire number of admissions.

Chart 4 shows the duration of the disease as calculated in 555 cases. The uncertainty of the disease is here shown. Some few endure for more than fifty years, while others are destroyed during the first year. The mean age in all these cases was 17.5 years; half the entire number of cases died between eight and fifteen years of epileptic life. This curve presents a marked double crest, and the

query naturally arises whether this is related to the double-crested form of the onset curves.

A list of the immediate causes of death in these cases would be tedious if given in detail; certain facts of considerable interest may be abstracted from such a list: (a) Pulmonary conditions are the commonest cause of death. Pneumonias of all sorts were reported 142 times, pulmonary congestion, eight times, and various other lung conditions, nine times. Tuberculosis of the lungs was mentioned 102 times and tuberculosis of other localities, nine times. (b) Sudden death occurred ninety-nine times; status epilepticus, fifty-nine times; series, thirteen times, and conditions which may be grouped under the head of mental disturbances with exhaustion, thirteen times. In all, causes of death related to epilepsy were reported 174 times. (c) Valvular disease of the heart, thirty-one times, and nephritis thirty-two times are the other important causes. The remainder of the list is made up of several minor groups of little interest for our purpose.

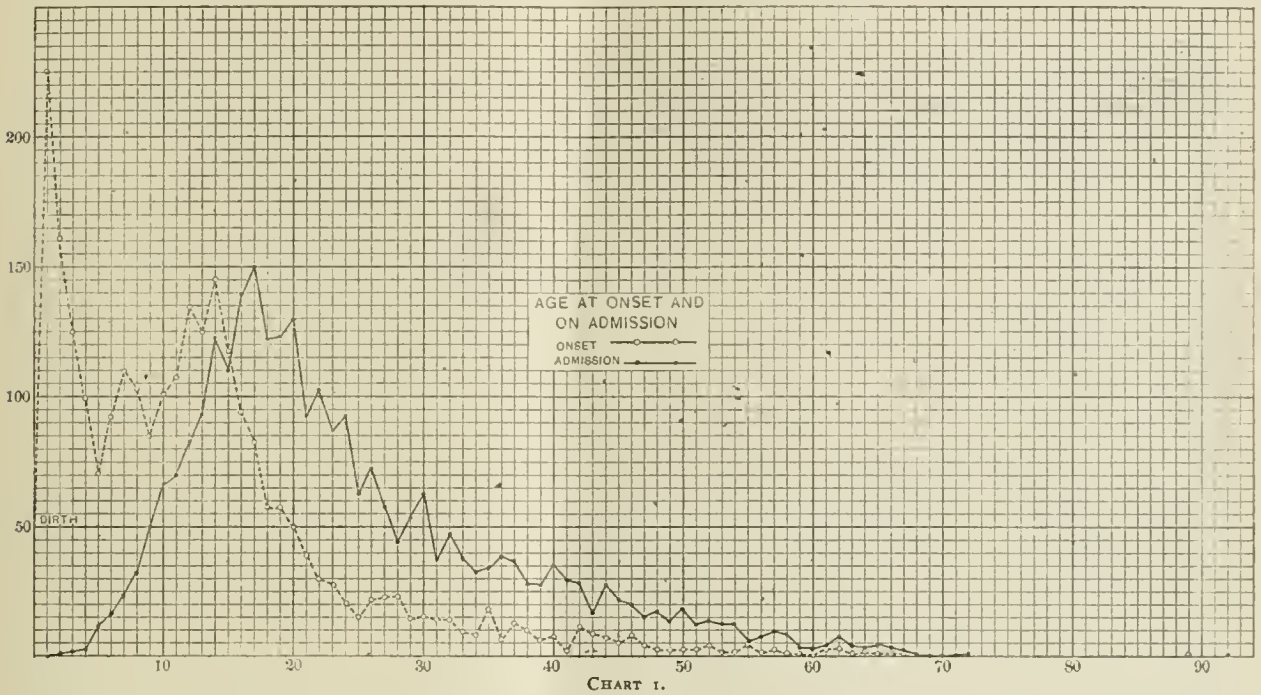

CHART 1.

It must be recalled that as two or more causes of death may be reported in the same case, the above figures do not represent individuals. It is evident, however, that the epileptic's lungs are his weak part and that pulmonary conditions are peculiarly dangerous to him. This is less apparent than had it been possible to show that back of the various lung conditions, other than pneumonia, there lay an epileptic conditions, status, series, and even single seizare in large part sequelæ of, and caused by, epileptic conditions status, series, and even single seizures, or the result of exposure while wandering in the automatic state associated with seizures. Pulmonary edema is not shown in the above figures, but it alone may be the cause of death within a few hours after its onset. The importance of this factor would be better understood were the figures for its occurrence made up, but in their lack it can only be said that it is a frequent and dangerous condition, following all forms of the epileptic attack, even single *grand mal* seizures. Its seriousness and frequency cannot be too strongly emphasized.

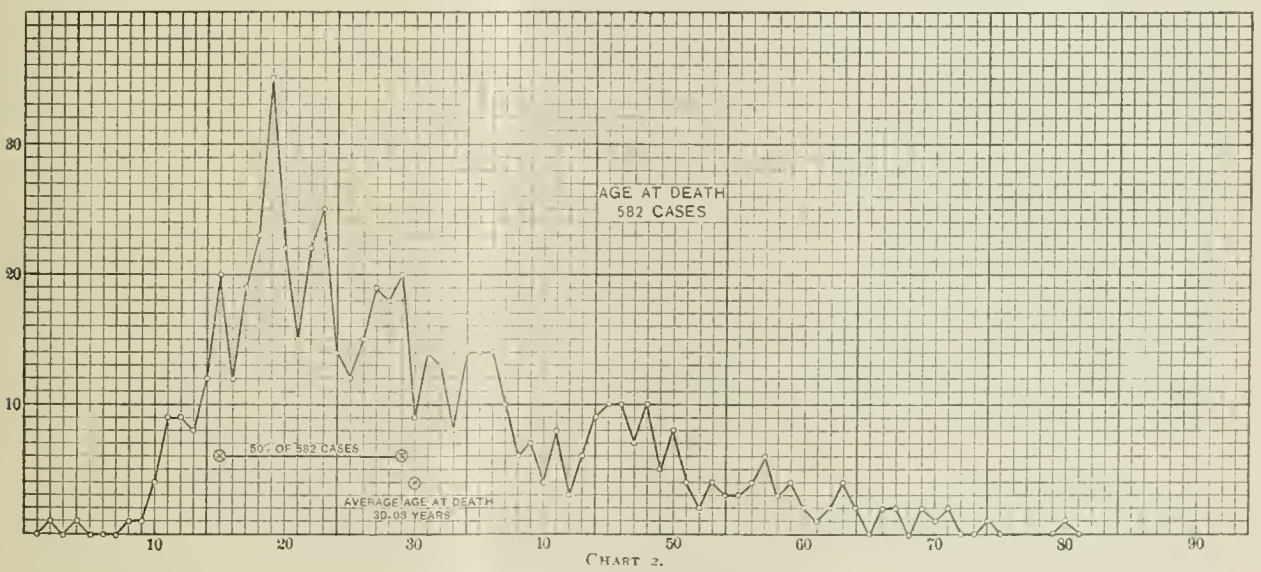

CHART 2.

As regards conditions directly related to epilepsy, it is interesting to note how much fewer are the deaths from status and series in the last few years than they were in the earlier years of the Colony. These are conditions which permit no temporizing and must be stopped as soon as possible.

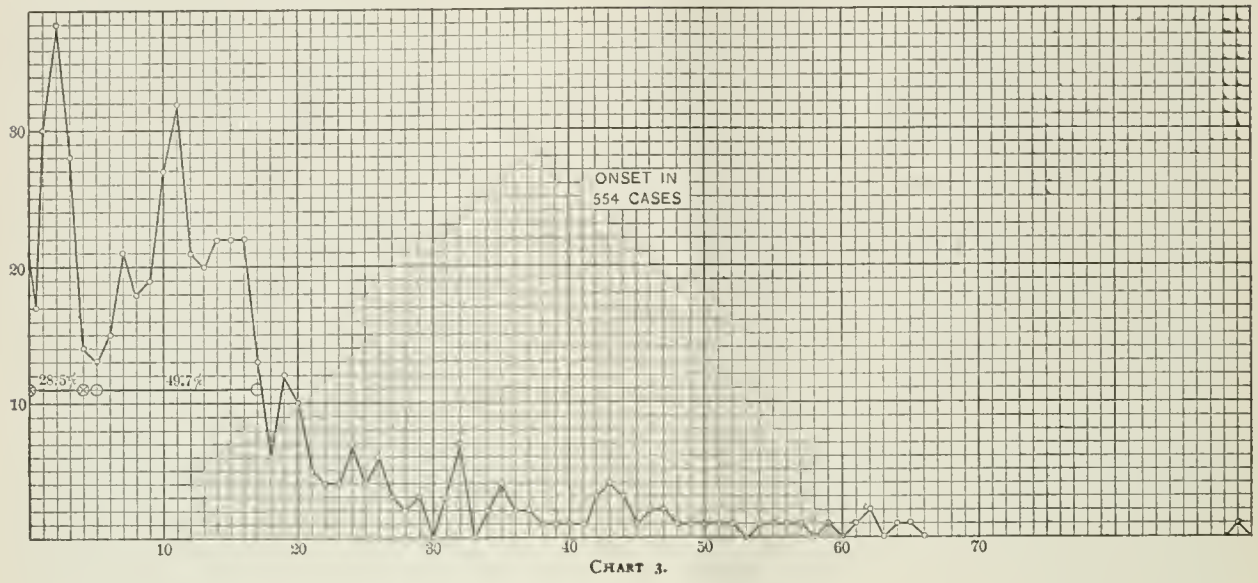

CHART 3.

Sudden death shows no diminution and evidently constitutes a quantity which cannot be controlled. There were, as above noted, about ninety-nine cases in which epilepsy was the real cause of death. At the basis of all was a seizure. The patient suffocated while helpless, met with an acident, burned himself, fell on the railroad tracks, etc. Acts done while in the automatic state sometimes bring fatal injury.

But besides these traumatic cases, there is a definite and fairly large group where neither accident of any kind nor suffocation can be assigned as the cause of death. The cause seems to be intrinsic rather than extrinsic. The questions raised by these sudden death cases are of great interest, both for the institution itself and from a medical and medicolegal point of view. The responsibility of the institution as regards the prevention of these deaths, the cause of death, and the anatomical findings, are the most important points to be considered.

CHART 4.

It is difficult to say how far preventive measures may be successfully carried out. There are cases of death in or following seizure in which the patient is seen to die. For example:

CASE I.—E. L., No. 1725, a female patient aged 48 years, had a seizure at 1:20 P. M. The nurse noted that her breathing was peculiar (in what way is not stated) and sent for the physician in charge of the service. When he arrived at 1:30 P. M. the patient was dead. The patient had previously had "fainting spells" and the autopsy showed cardiac and renal changes.

CASE II.—I. J., No. 1302, was found by the nurse at 4:15 A. M., in his bed, wet and soiled. He appeared to be recovering from a severe seizure. His respiration was rapid and he was gasping and moaning a good deal; he seemed to be in great distress, complaining of pain in his chest and spitting blood. Patient did not recover and had another seizure at 5:50 A. M. During this last seizure the patient suddenly relaxed, and the physician found him dead when he reached his bedside (not later than 5:55 A. M.).

In such cases as these preventive measures would be useless. Again, in a case of this sort, it is difficult to say what could have been done:

CASE III.—F. C., No. 2258, a male, was seen alive at midnight, and nothing unusual was noted. When the nurse made his next round at 1:30 A. M., he noted that the patient was not breathing in his usual manner, and on examination the patient was found to be dead. The physician's report states that the mouth and nose were clear, pillows wet with mucus, and urine had been voided. Face and neck were not cyanosed.

On the other hand, in a case of this character, close supervision might have prevented the death:

CASE IV.—M. van C., No. 1910, a female, was seen at 3 A. M., when she asked for extra bed covering, which was furnished. At 4:20 A. M. she was found dead, with her face down. There was some blood in the nostrils, and there was also some on the pillow. The face and the anterior portion of the chest and arm, except where pressure had

prevented, were purple. Pupils were equal and moderately dilated. There were petechial hemorrhages about the base of the neck.

A partial preventive measure is the use of hair pillows with a net covering, somewhat more pervious to the air than the ordinary pillow. This, however, is only a half way measure. Close and continuous observation seems to be the only possible means of preventing these deaths. The observation must be constant and close. It is not sufficient that the night nurse pay an occasional visit to the dormitories—for these accidents happen mostly at night, though also in the daytime. Each patient must be seen every few minutes, for, as has been noted, these deaths occur very rapidly at times. Hearing cannot be depended on—seizures not infrequently take place silently. Patients sleeping in the same room or dormitory are not to be depended on as safeguards, as they not infrequently fail to appreciate the responsibility or are not awakened by the seizure. In this connection, single rooms may be mentioned in order to condemn them. They have apparent advantages, and no doubt add greatly to the comfort of the patient, but he is much safer sleeping in a room with others.

It is an excellent rule that patients shall never walk afield without company. The writer, not many weks ago, was returning from a short trip to the village, when his attention was attracted to something on the fence at the roadside. That something was a man dead. As far as we could reconstruct the case the man had started to walk along the road, a much frequented highway, and had had a seizure. In some manner he had staggered out of the road, and coming nearly to the fence, had tripped or fallen with his throat across one of the wires. He was cut by the barbs, but the cause of death was strangulation. Swimming is a sport forbidden to our patients, but rules are made to be broken, so it seems, and the attractions of the swimming hole far exceed the appreciation of the danger, and a seizure in the water has in a few cases led to drowning. Walking on the railroad track is likewise a danger for the epileptic.

The symptoms or signs of a seizure presented in these sudden death cases rarely constitute a complete picture. Unfortunately, the written reports received for filing in the medical histories are incomplete in that negative findings are only occasionally mentioned; there is, thus, a feeling of doubt as to whether the hiatus was due to a failure to note a negative finding or whether the point was overlooked.

We have already discussed the finding of the body. The time elapsing between the hour last seen alive and the time of finding dead naturally depends on the closeness of supervision. Some were found alive; others on their faces, in a position indicating that suffocation was the cause of death; others were found on their backs, with suffocation a remote possibility. Fluid, mucus, foam, any of which may be at times stained with blood, either from a bitten tongue or from the pasage of red blood cells into the alveoli,* are commonly found.

Where mention is made of them, the pupils are dilated; the hands are sometimes clinched, with the thumbs in the palms. Voiding of urine is occasionally found, but feces and semen are comparatively rarely mentioned. Some significant feature peculiar to the case may be present. In one case, for example, the lower jaw was commonly dislocated in seizures, and when the patient was found dead, the jaw was found out of position.

A complete list of symptoms is practically never observed. Some are usually present, and careful search will reveal them. To insure more complete reports in these cases a printed form has been prepared for the purpose of guiding the preparation of reports and preventing omissions. This scheme of examination is herewith reproduced.

OUTLINE OF EXAMINATION IN CASE OF SUDDEN DEATH.

Name of patient.

Where, when and by whom last seen alive? What had been the condition of this patient during the last day of life? Where, when, and by whom was the patient found? Alive or dead? If alive, how long did he live?

Note the position and condition of the body in every respect, especially in regard to the following: Was the body on the back or on the face? Was face buried in the bedding or pressed into floor? Was there cyanosis of the face or of other parts of the body? Were there small point-like hemorrhages in the skin? (Examine especially the face, neck and shoulders.) Condition of pupils? Equal, unequal, dilated, contracted. Was the tongue bitten? Was there fluid about the mouth or nose, or spots from the same on the bedding? If so, character of fluid? Position of hands? Open, clinched with thumb out or in.

Was the body cold? Rectal temperature?

Was rigor mortis present (test stiffness)? Had urine or feces been voided? If a male, has there been an erection?

Describe any new wounds. Add any points not suggested above, which may throw light on the cause and manner of death, and its time. Did you attempt any measures of resuscitation? What and how long continued?

Autopsies were held in a considerable number (sixty-eight) of these cases of sudden death. On the whole, congestion and edema of all organs best sums up the findings. The leptomeninges are very commonly elevated by clear fluid and are also commonly congested. It should be remarked, however, that hydrops meningeus is also found in other of our cases. The lung condition is usually very striking; there is an intense edema and more or less congestion. Occasionally, small pneumonic areas are discovered. Hemorrhages in the lung tissue and beneath the epicardium are not uncommon. The heart was usually firmly contracted, though in a few cases the right side was greatly distended. Valvular changes were not common, but nephritis was more commonly found.* The lymphatic tissues were not uncommonly hyperplastic, enlarged mesenteric and celiac glands being frequent; the solitary follicles of the lower portion of the digestive tract are often very large and numerous. Persistent thymus, however, has been in these and in all our cases a rather exceptional finding.

In summarizing the points which the writer wishes to bring out, the following may be presented:

1. The duration of life after the onset of the disease may be several years, but as the onset is

*Red blood corpuscles are almost always found in the pulmonary alveoli, accompanying the edema and congestion typically present in these cases.

*In a forthcoming paper on "Postepileptic albuminuria" the question of a nephritis in some of these cases is discussed.

very common in the early years of life, the net result is the premature death of the epileptic as compared with normal people.

2. The causes of death in epileptics are quite largely associated with the disease itself, and may be divided into two main groups, pulmonary conditions and conditions of purely epileptic character.

3. Pulmonary conditions usually have at their foundation the pulmonary edema which is so often associated with seizures, etc., and hence are secondary to the epilepsy. Exposure while helpless or automatic after a seizure may also be responsible for lung conditions. It is possible that the frequent congestions and edemas occurring in these lungs make the soil fertile for the tubercle bacillus.

4. Death is imminent at the time of seizures, unless help is at hand. The cause may be traumatic, suffocation may take place, or death may occur without any apparent cause.

5. Epileptics dying in seizure will usually show some, but rarely if ever all, of the signs of seizure. The anatomical findings are edema and congestion, and often the diagnosis of seizure death has to be made largely by exclusion.

6. The moral may be pointed from these facts that the epileptic should be by himself as little as possible. His walks should be in company or else in frequented places, and his repose should be under the watchful eye of a night nurse, or at least in the same room with several other patients.

OBSERVATIONS REGARDING THE FINGER TONE.*

By GEO. O. WILLIAMS, M.D.,

GREENE, N. Y.

THIS paper is a résumé of some facts and some inferences developed while investigating the tone that is heard by the observer when the ball of the finger is lightly laid upon the diapraghm of a stethescope. The middle finger is selected for this purpose, for convenience only, as the tone is heard when any of the fingers or toes are used on any other part of the body. The instrument known as the Bolles' stethescope gives the best results. It should be held by the shank. The tone is interfered with when any portion of the observer's hand touches the rim of the bell.

The finger of the patient must be laid *very lightly* on the diaphragm. Heavy pressure complicates the tone. The hard rubber diaphragm of this instrument is sensitive enough to transmit the sound of the feet of a fly crossing it.

The tone may be described as a continuous hum without a distinguishable pulsation. It is certainly connected with the circulation. For the sake of theory it may be reasonably assumed that it arises from the transmission of the blood current through the capillaries. The varying pitch and volume of the tone seem to depend upon the volume and intensity of the current. The following may be considered as facts:

(1) The tone is audible in the living. It is inaudible in the dead. (2) It is audible on any portion of the body in varying degrees. (3) It is greatly increased if the base of the finger is wound with an elastic band. The difference in the tone is surprising. (4) A long series of observations have served to establish what may be considered a normal tone. (5) The tone is certainly modified by pathological conditions. (6) It averages louder in the male than in the female, and in early old age than in youth. (7) It is absent in collapse from any cause. (8) Exposure to cold reduces or entirely removes the tone. As for instance the exposure of the fingers to severe weather in winter.

The following, while not absolutely proven facts and perhaps insufficient to warrant conclusions, may, however, serve in determining whether the finger tone has a clinical value and assist in establishing what that value may be: (1) A diminished arterial current reduces the tone. This is true whether the cause lies in the heart or beyond the heart. Local arterial obstruction destroys the tone beyond the obstruction. In a case of extensive destruction of tissue from infection of the hand the tone was scarcely audible. Its mate's tone was normal. In a case of posterior tibial embolism the tone was audible above and absent below the plug. Gangrene subsequently occurred.

In a case of paralysis of the left arm which was seen three hours after the commencement, the tone was diminished as compared with the right fingers. In the same case, seen a year afterward, when motion and sensation were restored, the tones in right and left fingers were uniform. (2) It was absent in a newly born infant and inaudible in the mother just after delivery. (3) It was diminshed in three cases of chronic albuminuria with edema of hands and feet. (4) In two cases of femoral thrombosis the tone was intensified in the toes. The observations were made shortly after the onset. (5) In several trials on individuals under alcoholic excitation the tone was diminished. It became normal when the men became sober. (6) It was greatly diminished in cases of typhoid with high temperature, 104°-105°. In one case the tone was scarcely heard. This patient died from hemorrhage in a few days. In a case of pneumonia complicating measles, with a temperature of 104.5° the tone was enormously increased. After recovery the tone became normal. It is probably true that the average tone in high temperatures is less than normal. (7) In several cases of mitral disease the tone was exaggerated. How constant this may be requires more observation.

The following experiment was undertaken to ascertain the effect of severe exercise upon the tone. In making these observations the letter X was used to denote a normal tone. A diminished tone was indicated by one or two minus signs before the X, thus: — X, — — X, the latter being used to signify a minimum tone. An increased tone was indicated by XX and XXX.

Six young football players were selected. Their readings were as follows: No. 1, X; No. 2, XX; No. 3, X; No. 4, X; No. 5, —X; No. 6, —X. No. 2 had a history of etherization for appendicitis a year previously, and subsequent shortness of breath. He had an intermitting heart, and was a liberal smoker. No. 3 had a severe single pneumonia 20 months prior to this test. It will be noticed that No. 2 gave a finger tone of XX. His father has mitral disease with an exaggerated finger tone. It will be noticed also that No. 3 gave a normal tone.

The exercise consisted in running 30 rods and up a flight of 16 steps. After the exercise the readings were: No. 1, X; No. 2, X; No. 3, XX; No. 4.

*Read at the meeting of the Sixth District Branch of the New York State Medical Association, Binghamton, October, 1908, and at the Chenango County Medical Society, in June, 1908.

—X; No. 5, ——X; No. 6, ——X. It will be noticed that No. 2, who gave an overloud tone prior to the exercise, gave a diminished tone after it. No. 3, with a previous pneumonic history, gave an exaggerated tone after the exercise. This was the only one who gave an overloud tone after the exercise. There are several inferences that have come from careful daily use of the instrument for nearly three years.

These must not now be accepted as authoritative or absolutely conclusive. They are, however, probable: (1) An overloud tone in middle or early life should be regarded with suspicion. Pulmonary or hepatic lesions may be present. (2) In life insurance it is an important factor and should weigh against the risk. (3) An overloud tone may accompany mitral, and a greatly diminished tone, aortic disease. A general statement may be true, overloud tones denote venous obstruction and that diminished tones denote arterial obstruction.

The limitations of general practice do not afford the same opportunities for investigation that are found in large hospitals. This subject then may be left to some careful and painstaking student with a taste for research, to determine what the clinical value of the finger tone may be. There is much to be learned about it before it can be discarded as valueless.

CONTACT INFECTION IN AMEBIASIS.

By WILLIAM ALLAN, A.B., M.D.,

CHARLOTTE, N. C.

PROFESSOR OF PARASITOLOGY, NORTH CAROLINA MEDICAL COLLEGE.

Amebiasis is classed as an infectious disease, but the exact knowledge of the ways in which it is spread is not as full as we could wish. The infecting organism is cast out in the feces, as is the typhoid organism, and by analogy we should expect the disease to be spread in the same ways, viz., by the water supply, raw food, contact, and insects.

It is the third proposition, contact infection, that I wish to discuss here. Schaudinn has shown that when amebæ in the motile or vegetative state from a recent stool are fed to cats no infection follows, but when they become encysted through drying infection is possible (Manson, "Tropical Diseases," 4th edition, p. 444). Schaudinn has also shown that *Entameba histolytica* multiplies by budding and that these buds, when pinched off, at first become encysted and are capable of infecting cats (Calkins, "Protozoology," 2d edition, p. 299). The chance of infection from "encysted buds" would probably be less than that from the organisms which had become encysted during the vegetative stage, owing to hostile environment. How long it takes vegetative amebæ, on being cast out in the feces, to encyst sufficiently to pass through the gastric juice is not known. Judging from the effect of cold slides or a little acid urine mixed with the feces, it does not take very long.

Contact infection in amebiasis should be much less common than contact infection in typhoid fever, because of the size and shape of the organism and of the preparation which it must first undergo. But the idea of contact infection will not seem strange to those who have seen persons handle soiled linen, empty and clean vessels of all descriptions, used as commodes and urinals, and then prepare or eat food without first washing their hands. When it is the dysenteric herself who prepares and serves the food the chance of contaminating it is, of course, much more constant.

The occurrence and distribution of the following four cases of amebiasis are unusual in my experience, and I think significant of contact infection:

Brick Row in Charlotte is a long building, housing from fifteen to twenty families. Each family has a front room and either one or two small back rooms. Front and back galleries run the length of the building. City water supply. Sanitary closet at one end of the building. In May, 1908, I was called to see G. S., white, female, age 8 years, who had had dysentery several months. Examination for amebæ at this time was negative. I saw the case again in August, 1909, and was told that the little girl still had the same dysentery. Examination of the feces showed blood, mucus, and *Entameba histolytica*. Blood examination showed hemoglobin 75 per cent., eosinophilia 11 per cent.

In March, 1909, this little girl's small brother, aged 22 months, contracted dysentery. Examination of the feces (August, 1909, at the time of the girl's examination) showed blood, mucus, and *Entameba histolytica*. Blood examination showed hemoglobin 75 per cent., eosinophilia 20 per cent.

As the mother had a still younger baby to nurse, as well as the cooking, washing, and cleaning to do, the girl had practically entire charge of the boy. She dressed him, fed him, and cleaned him up after a bowel movement. This family moved into Brick Row about a month after the girl first contracted dysentery.

On August 15, 1909, I was called to see Mrs. B., who lived in the opposite end of Brick Row. She was a widow with four children; three, aged respectively 16, 12, and 8 years, lived with her at home, while the oldest daughter was married. The mother gave a history of chronic recurrent dysentery for the past eight years. She had been living in Brick Row one year. The present attack began August 1, 1909. She was greatly prostrated and confined to bed a part of the day by the frequent and painful bowel movements. Examination of the feces showed blood, mucus, monads, and *Entameba histolytica*. Blood examination showed hemoglobin 75 per cent., cosinophilia 2.8 per cent.

On August 8, 1909, the 16 year old daughter, a mill hand, developed an acute attack of dysentery with 8 to 15 bloody mucous stools a day. She had never had dysentery before. At this time both the mother and daughter were preparing and serving the food, while the daughter emptied the tin bucket used as a commode. Examination of the daughter's feces showed blood, mucus, monads, *Entameba histolytica*, and eggs of *Necator americanus*. Blood examination showed hemoglobin 70 per cent., eosinophilia 5.2 per cent.

At this time I interviewed all of the inhabitants of the Row. No other person in the place either had dysentery or gave a history of dysentery. The majority of them had lived there more than eighteen months.

Therefore, it would seem that: (1) The original case of dysentery in each of these two families had been contracted before they moved to this locality; (2) that during the past eighteen months the only cases that had developed in the Row had been in the families in which there was a source of infection in the person of a chronic ameba carrier; and (3) that the last two cases had become infected from the first two by contact.

A CASE OF PUERPERAL SEPTICEMIA TREATED WITH DIPHTHERIA ANTITOXIN—RECOVERY.

By EDWARD M. DEACON, M.D.,

BIRDSBORO, PA.

Mrs. P., aged 26—Primipara—physical condition not robust. After having severe false pains for three days before the regular labor pains appeared, was delivered of an eight-pound boy at 1 o'clock A.M., January 6, 1909. The labor advanced normally until the head of the child reached the pelvic floor. At this juncture the pains became weak and irregular. After waiting about an hour, chloroform was administered, and under strict antiseptic precautions, forceps were applied. Notwithstanding a slow and careful delivery, a complete laceration of the perineum resulted, about an inch and a half in length. This was repaired immediately. The placenta was removed intact.

For the first two days the patient rested well except for a slight headache. On the third day she complained of much headache and soreness in the abdomen. Temperature 100°. No chills. An ice bag was applied to the abdomen and a saline purgative given. Vaginal douches of carbolic acid, 1 to 20, were ordered. On the fourth day she complained of chilliness. Temperature 100.5°. The lochial discharge appeared normal in quantity and character. On the fifth day pain and tenderness grew worse, her temperature was 101°. On the sixth day headache was very severe. The tongue was dry and brown. The abdomen was slightly distended. The appearance of the lochial discharge had not altered. The temperature was 103°. Under chloroform anesthesia the uterus was curetted thoroughly, and irrigated with very hot creolin solution, one drachm to the quart. Unguentum Credé was applied to the abdomen and inner side of the thighs, night and morning. Calcium sulphide, one-half grain, was ordered every two hours, and strychnine, 1/40 grain, every three hours. Magnesium sulphate was given freely. High enemata of hot water containing turpentine were used by means of a rectal tube in order to overcome the abdominal distention. The ice bag was kept constantly on the abdomen.

From this time until January 18, intrauterine douches of creolin were used twice daily. Vaginal douches were used every three hours. The treatment remained the same as stated above. On January 18 the temperature was 105.5°. Pulse 160. The abdominal distention was enormous. There were repeated chills. The patient was stupid. There was severe abdominal pain. The uterine discharge was very profuse and purulent, imparting a marked septic odor to the sick room. With the patient in this extreme condition I decided to use injections of diphtheria antitoxin, although I had never heard of its having been used in cases of this kind before There were no diphtheritic symptoms present. Accordingly on January 18, 9,000 units of antitoxin (diphtheritic) were used. Five thousand in the morning and 4,000 in the evening. On January 19 the morning temperature was 104.5°. Pulse 148. The patient was not quite so stupid. Ten thousand units were given (5,000 in the morning and 5,000 in the evening). On January 20 the morning temperature was 104°. Pulse 140. The patient was much brighter, and took more nourishment. Ten thousand units (5,000 in the morning and 5,000 in the evening) were given. On January 21 morning temperature 102°. Pulse 120. Abdominal distention much less. Ten thousand units (5,000 in the morning and 5,000 in the evening). January 22 morning temperature 100.5°. Pulse 100. Very little purulent discharge. Tongue becoming moist and less coated. Four thousand units in the morning. January 23: Morning temperature 98.6°. Pulse 80. Patient very bright and in good spirits. Abdominal distention and soreness growing less. An injection of five thousand units was given in the morning.

January 24, 25, 26, 27, and 28 the temperature remained normal. Purulent discharge ceased on the 24th, and did not reappear. No antitoxin was used on these dates. January 29: Morning temperature 101°. Pulse 110. Fearing the new foci of suppuration were becoming active, I deemed it necessary to inject 3,000 units. January 30: Temperature 100°. Pulse 98. Patient feels comfortable. Very little abdominal distention. Ten thousand units (5,000 morning and evening). January 31: Morning temperature 99°. Pulse 80. Nine thousand units (4,000 in the morning and 5,000 in the evening). February 1: Morning temperature 99°. The patient is quite bright and feels comfortable; her appetite is very good. The use of antitoxin was now discontinued.

The temperature remained at 99° for ten days, when it became normal and remained so. The abdominal distention had disappeared now. For a time there was some tenderness on pressure in the left ovarian region, but this disappeared eventually. About the middle of February the patient was allowed to sit on a chair, and she said that she felt quite well.

Throughout her illness the patient was kept on a liquid diet consisting of milk, egg-nog, and beef tea. No solid food was allowed until the temperature had remained normal for a week. While the antitoxin was being used, a combination of strychnine, glonoin, and digitalin was also used very persistently.

Fortunately cases of puerperal septicemia are rare in private practice. This was my first and only case in fifteen years' practice, and I cannot account for it as strict antiseptic precautions were used at the very beginning. It is possible that the infection occurred at the time that the perineum was ruptured, thus coming from the contents of the rectum.

Many cases have been reported in which Marmorek's serum was used, with variable success. This serum was not at hand when I wanted to use it. The profound septic condition of my patient is what led me to select diphtheria antitoxin, although in using it I felt it was in the nature of an experiment, and so informed the family. The prompt action of diphtheria antitoxin in stopping the suppurative process in this case leads me to venture the opinion that it will be equally valuable in all septic conditions of a profound type, not only those occurring during abortion, and parturition at full term, but also those due to infected wounds in any part of the body. In using antitoxin in these cases, it must be used fearlessly and persistently. A total of seventy thousand units was used in the case which I have just reported, and at this writing, October 18, 1909, the patient is in the best of health, and she has never experienced any ill effect whatever from the treatment.

THE DISPOSAL OF SEWAGE.

In the same degree as the trend of population is in the direction of cities, so is the question of the disposal of sewage of increasing importance. The proportion of persons living in towns advances yearly in all civilized countries, and the responsibility of conserving the health of the multitude is thrown to a large extent upon the urban authorities. In most instances these have proved mindful of their responsibilities, and on the whole the physical welfare of modern citizens is carefully safeguarded. There is, however, a disposition to overlook somewhat the danger that may accrue to the community at large from carelessness in regard to sewage disposal. As a matter of fact, there is no part of the sanitary régime of a crowded center which requires more and closer attention than this matter of sewage disposal. It is extraordinary that, with the impetus which has been given to sanitary science within recent years by means of knowledge gained from practical experience, the lesson taught has not more often been taken advantage of. There are still cities of large size and of great wealth in which the methods of getting rid of their sewage are, to speak mildly, primitive. It may now be taken almost as an axiom in writing on this question, that when sewage is discharged into lakes, rivers, or harbors in proximity to a city or a town, such matter should in every case be disinfected or treated in one way or another, so that pathogenic bacteria are destroyed or destroyed as effectively as possible. Measures of this description are absolutely indicated whenever there is the slightest possibility of pollution of water supplies or of shellfish beds.

It took a very long time to educate or even partially to educate the public with regard to the danger of a contaminated water supply. Many persons are still skeptical on the point, and it is perhaps only those who have witnessed an epidemic of typhoid fever or cholera brought about by polluted water who recognize the need of carefully safeguarding the water supply. Physicians, sanitarians, and those members of the general public who have taken the trouble to investigate the subject are fully agreed that the water supply of every large city should be delivered to the consumer as free from noxious germs of every description as it can be rendered. But there is no agreement as to the most efficacious and readiest way of effectively disinfecting sewage. The British Royal Commission on Sewage Disposal which sat for many years and whose members assuredly deliberated on the question more thoroughly than it had ever been threshed out before, concluded that on the whole the old-fashioned land treatment of sewage was the best, and, of course, there are none or few who will dispute the statement. It is Nature, doing her own work in her own way. But even with the improved methods of land filtration and disinfection, there are frequently, so far as cities are concerned, insuperable obstacles to carrying out this system.

The United States Geological Survey of the Department of the Interior has recently published a paper on the Disinfection of Sewage and Sewage Filter Effluents, written by Mr. E. B. Phelps, which is in part an excellent review of most of the methods now in vogue for disinfecting sewage. Mr. Phelps is of the opinion that both improved standards in sanitation and improved methods of disinfection will operate to increase the existing minimum requirements with respect to sewage disposal, but in the meantime a thorough knowledge of disinfection methods and experimentation on the improvement and cheapening of such methods will do much to hasten their general adoption. Mr. Phelps points out that chemical disinfection offers a means whereby a reasonable bacterial purification may be accomplished without complete purification of the organic matter. After considering the merits of other forms of chemical disinfection of sewage, which it must be understood is not a substitute for sewage purification in the ordinary sense of the words, but rather a finishing process, Mr. Phelps records his judgment that calcium hypochlorite, or commercial bleaching powder, is the most efficient agent. It has greater germicidal efficiency than equivalent amounts of free gaseous chlorine, chlorates, or perchlorates, and is more certain than the potassium and sodium hypochlorites.

The result of experiments made with bleaching powder as a sewage disinfectant showed that the application of three parts per million of available chlorine in the form of bleaching powder to a trickling-filter effluent effects satisfactory disinfection. The cost of disinfection ranges from $1 to $1.50 per million gallons of sewage, depending chiefly on the size of the plant. Effluents of higher degrees of purity can be disinfected at a still lower cost. Crude sewage to be disinfected satisfactorily requires the removal of over 98 per cent. of its total bacteria. This may be accomplished by the application of from 5 to 10 parts per million of available chlorine, the amount depending on the character of the sewage. Such disinfection costs from $1.50 to $3.50 per million gallons. The disinfection of septic sewage requires the application of from 10 to 15 parts per million of available chlorine, but if no further purification is required than that given by septic action and by disinfection, it is better to reverse the processes by disinfecting the crude sewage before it enters the tank. It is considered that the action of the chlorine on the typhoid bacillus is as satisfactory as its action on the sewage bacteria as a whole.

Mr. Phelps holds that his experiments with bleaching powder as a sewage disinfectant have been so successful as to justify the belief that the results are of general applicability. The experiments were in progress for a considerable period of time, were continuous, and the conditions resembled in most respects what would take place in ordinary working practice. It would appear to have been proved that bleaching powder is an effective and cheap finishing disinfectant of sewage, and compares very favorably with other chemical processes with the same object in view. If it will act as well in practice and on a large scale as Mr. Phelps predicts, then there is every reason to advocate its employment. It is a healthful sign that in all parts of the civilized world increasing interest is being taken in the question of sewage disposal, and painstaking experiments such as have been carried out by Mr. Phelps bring nearer the time when sanitation will be ideal and when waterborne diseases will be finally abolished.

REST IN TUBERCULOSIS.

It would seem that the general management of patients with active tuberculosis has been sufficiently agreed upon during the last few years to insure against any frequent sins of omission or commission in this respect by the practising physician. Yet a paper by Francine in the *International Clinics* (Nineteenth Series, Vol. III) shows that this is not at all a general fact; he mentions numerous instances of patients seen by him in consultation with general practitioners who have sinned against the broad principles of treatment generally agreed upon. The most obvious mistake noted by the author has been the tendency to treat symptoms by the administration of drugs and the disinclination to advise complete rest in active tuberculosis. Francine very properly asks, what is the use of giving cough medicines so long as the process in the lungs, the cause of the cough, goes on actively; what is the use of prescribing atropine or other drugs against night sweats, when the hectic fever that is at the foundation of the symptom is not treated; finally, what is the use of prescribing stomachics and gastric sedatives, when high fever and the toxemia it implies go on unchecked?

Rest is the part of the treatment which Francine insists upon, whether symptoms or the general course of the disease are considered. In his own words: "Bed, let me say, is the word to which I have been leading. You can do nothing with a patient with active tuberculosis who has much fever until you put him in absolute rest. . . . So for fever, bed; for cough, bed; for night sweats, bed; for weakness and anemia, bed; emaciation, bed; irritable stomach, bed; and so on through the whole list." This advice is summed up with the statement that all patients with a temperature consistently rising above 100° should be absolutely confined to bed. Exercise should be instituted only when the pulse and temperature are practically normal, for before that time it can only do harm.

This advice contains a proper appreciation of the pathological process that goes on in tuberculosis. The disease is, of course, a specific infection, and so far we have no specific *cure* for it, though in tuberculin we have a specific *drug* of high potency and little understood use. The fundamental idea, therefore, should not be to combat that or this untoward symptom, but to put the body into such conditions as would enable it to fight the infection by its natural protective agencies. Rest is the most important single element in obtaining these conditions in the case of tuberculosis just as it is in the case of typhoid fever, so long as the process is active enough to cause an abnormal waste of tissue and energy, as evidenced by fever and its concomitants. Fresh air and abundant diet are other more obvious portions of this régime, while the numerous special agents, whether mechanical or pharmacopeial, are the least important so far as the fight against the causative agent of the symptoms is concerned. In calling attention to this fact Francine has laid proper stress on the principle of treatment which is of most promise in dealing with tuberculosis.

The Importance of Clean Hands.

Writing in the *Dietetic and Hygienic Gazette* for December, 1909, R. E. Eccles of Brooklyn lays stress on the need of keeping one's hands clean, not figuratively, but literally, clean. Dr. Eccles most assuredly is a hard and fast believer in the dictum ascribed to good John Wesley that cleanliness is next to godliness, and especially cleanliness with regard to the hands. Indeed, so convinced is he of the supreme importance of this matter, and so earnest is he that the gospel of clean hands should be spread far and wide, that he advises the editors of popular magazines to inaugurate a crusade against dirty hands, in order that the bearing of the matter with respect to public health should be brought home to the largest possible audience. However, dirty hands, according to the popular and obvious conception of the word is not what Dr. Eccles meant by his reference to the subject. It is the unseen "drit," the Saxon word from which the modern term dirt is derived signifying excrement, to which the writer alludes; in fact, his article is an appeal for the dissemination of the principles and practice of asepsis among laymen. It is pointed out, and with striking truth, that dire diseases are not infrequently spread by means of infected hands. Many of the destructive epidemics of typhoid fever have been due to the hands of a milker infected with the germs of the disease. Flexner has gone so far as to declare that "perhaps the chief single compelling phenomenon is that of the microbe carrier. . . . He has been found to disseminate typhoid fever, dysentery, plague, cholera, influenza, spinal meningitis, and in certain localities a host of protozoan diseases." Cooks, bakers, and dairy workers thus infected are those whose callings render them obvious sources of danger to the public at large, if they do not thoroughly and frequently cleanse their hands. It is without doubt also perfectly true that the ordinary individual is often unaccountably lax in performing his ablutions in such a way that, from the health point of view, he will be no menace to his fellow men. On occasions the failure to achieve this object is owing to the fact that the means for so doing are absent. Eccles recounts his experience on a large floating ocean pal-

ace in regard to cleanliness of passengers as to hand washing. Some of the tales unfolded recently in the lay journals of New York as to the arrangements made for the convenience of steerage passengers on Atlantic liners go to show that these passengers are not afforded the necessary facilities for keeping themselves clean. A writer in the *Sanitary Record* of October 28, 1909, on life in the steerage of a large modern steamship plying from Liverpool to Montreal, states that for the 120 or so men aboard at the British end of the steerage there were provided but six basins in which to wash. It stands to reason that in like circumstances it would be impossible to cleanse one's hands properly, even if one had the will. There is little doubt that disease is spread, perhaps widely, by people who neglect to wash their hands at fitting periods. A great deal of this neglect is due to ignorance of the dangers which may accrue therefrom. The first and most essential step to be taken is to educate the community at large to a sense that it is the manifest duty of every person to maintain himself in such a condition of cleanliness that he will not be a factor in the spread of disease.

The Local Use of Chloral Hydrate.

Though chloral hydrate may be ranked as one of our best known and most widely used narcotics, its local actions upon bacteria and upon tissues does not seem to be very generally appreciated. For a number of years various practitioners have been using solutions of this salt for local application to contused and inflamed tissues, and these claim that in such conditions as bruising of soft parts, burns, sunburns, and even acute arthritides it is a decidedly effective anodyne. In the *Münchener medizinische Wochenschrift* for November 23, 1909, Heller describes several ways in which the salt is of value for its local activity. He first calls attention to its powerful deodorizing effect, he having for many years used five per cent. solutions for the preservation of pathological specimens, and as a useful and effectual wash for the hands, hair, and beard of the pathologist, removing completely the clinging odors of the autopsy or dissecting room. Besides its use in the laboratory, he says it is of great value in the clinic, especially in cases of tonsillitis and pharyngitis. His procedure of treating such cases consists in taking into the mouth a small amount of a two and a half per cent. solution of chloral hydrate, and, after throwing the head back, of swishing the fluid about in the throat without gargling. In the same article Professor Quincke notes that he has used the drug for sore throats for many years with excellent results. In lues, diphtheria, and Vincent's angina, Quincke still applies bichloride, but in all other forms of sore throat, and in those cases of lues, also, in which mercury is contraindicated, he has used a two per cent. solution of chloral, by means of a powerful spray. In the nose in diphtheria and other purulent processes a one per cent. solution in normal saline is used, while in ulcerative stomatitis, especially of mercurial origin, a two per cent. spray, or a one per cent. wash is of great value. This insures mechanical cleansing, disinfection, and deodorization, and, following the initial burning, a decrease of pain. Chloral would thus appear to be an ideal agent for the treatment of angina, and may prove of value in other forms of inflammation of mucous membranes.

News of the Week.

Vital Statistics for New York City.—Statistics were issued by the Health Department of New York City, January 1, which showed that the city's birth rate is decreasing. In the last year there were 41,483 marriages, an increase of 3,984 over 1908, with 123,433 births, a decrease of 3,429 under the previous year. The figures also showed that the total number of deaths during 1909 in the city was 74,105, as against 73,073 in 1908, an increase of only 1,023. There was a decrease in the death rate to 16.23, the lowest in the history of the city. In 1908 the death rate was 16.52, the second lowest in the history of the city. The mortality statistics showed an increase in deaths from whooping cough, cancer, acute bronchitis, bronchial pneumonia, and Bright's disease. The percentage of deaths from typhoid fever and measles remained about stationary, while from scarlet fever, diphtheria, influenza, all forms of tuberculosis, organic heart disease, accidents, suicides, and homicides they decreased.

Low Death-Rate in Philadelphia.—The death-rate for the city of Philadelphia for the year 1909 was 15.85 for each 100,000 of population, being the lowest in the city's history. In 1908 the death-rate was 17.16. The total number of deaths in 1909 was 24,814. A large share of the reduction was due to precautions taken to prevent the spread of communicable diseases. The number of deaths from diphtheria increased from 473 in 1908 to 514 in 1909. The death-rate from typhoid fever was reduced from 35.5 in 1908 to 22 in 1909. There were fewer deaths also from tuberculosis, pneumonia, and scarlet fever. Infant mortality also was reduced.

The New York Milk Commission has issued a statement as to its activities in procuring certified milk for New York City. In 1900 the Commission was organized. In 1901, 3,000 quarts of certified milk was supplied daily by nine dairymen. In 1902, ten farms produced 4,300 quarts daily; in 1903, twelve farms produced 5,138 quarts, and in 1904 fifteen farms 7,062 quarts. The sale then increased and finally fell off slightly, but last fall seventeen farms were selling 8,500 quarts of certified milk daily. The object of the Commission is to aid in the production of clean milk free from pathogenic or disease-producing bacteria. At present there are more than fifty milk commissions in the United States endeavoring to improve dairy conditions and the production of milk, and yet the production under these commissions is only a fraction of 1 per cent. of the 10,000,000,000 or more quarts of milk annually consumed in this country.

Philadelphia Bureau of Health.—Mr. John A. Vogelson has been appointed Chief of the Philadelphia Bureau of Health in succession to Dr. A. C. Abbott, who resigned some months ago. He will devote himself especially to a solution of the sanitary problems affecting the public health while the medical work will be in charge of the Chief Medical Inspector, Dr. A. A. Cairns.

Brooklyn Health Department Moves.—The Brooklyn Health Department, which has been located on Clinton street near Fulton for the last eighteen years, has moved to the new Municipal building at the Flatbush avenue extension and Fleet place.

New Tuberculosis Exhibit.—The Charity Organization Society plans to display its educational

tuberculosis exhibit in every district of Manhattan. This exhibit received first prize at the International Congress in Washington, but time, money, and the skill of photographers and artists have improved it, and it bears little likeness to the Washington exhibit. Now, after being shown in the heart of the east side and in the center of the financial district, it has been placed in 714 Fifth avenue, between Fifty-fifth and Fifty-sixth streets. The exhibit is open from 10 A. M. to 6 P. M. Phonographic lectures and demonstrations of pictures and models are given at frequent intervals.

The Royal College of Surgeons of London has recently changed its long standing regulations regarding its museum on Lincoln's Inn Fields, so as to give much greater privileges to women. Whereas previously women were admitted to the museum only at certain stated hours, now any woman medical graduate is admitted at all hours at which the museum is open and women medical students may obtain the same privilege on application to the secretary, if recommended by the dean of their school.

Insurance Sanatorium Legal.—Superintendent of Insurance Hotchkiss's refusal to grant the Metropolitan Life Insurance Company permission to acquire real estate on which to erect a sanatorium for the treatment of its employees suffering from tuberculosis has been disapproved by the Appellate Division, Third Department. The matter was remanded to him for further consideration. Supt. Hotchkiss's decision was based on his construction of a section of the insurance law, which prohibits an insurance corporation from purchasing and holding real property, except such as shall be required for the transaction of its business. The company in its application stated that it might decide to treat at the proposed sanatorium selected cases from among its policy holders.

A New Clinic for Detroit.—The Board of Health of Detroit has voted to establish a mother's clinic, where mothers may receive aid and instruction in the care of their babies. Dr. Francis Duffield will have charge of the clinic and the Visiting Nurses' Association will supply a nurse. The board also decided to establish, within the next few weeks, a clinic for the examination and treatment of all public school pupils suffering from eye and ear troubles. In cases where it is found necessary for the pupils to wear glasses they will be provided free, if the parents are too poor to purchase them. The board will cooperate with the board of education in the establishment of an open-air school for tuberculous children.

Bryn Mawr Hospital.—Mrs. A. J. Cassatt, widow of a former president of the Pennsylvania Railroad, has donated to the Bryn Mawr Hospital, as a memorial to her husband, a plot of ground adjoining the hospital, together with a building that can be converted into a children's ward, as well as an endowment sufficient to maintain the ward in perpetuity.

A New Hospital in Gulfport, Miss., has just been opened. It is known as the Kings Daughters' Hospital, as it was made possible by the work of that society.

"Hippocrates" is the title of a new medical journal of Constantinople, the first one published in the Greek language in Turkey. To students of medical history this new periodical will be of interest, because part of it is to be especially devoted to ancient Greek medical literature, publishing original studies and researches in this field made by physicians of Greece, Turkey, and Egypt. Dr. A. Rose of this city is named as one of the contributors.

Dr. E. A. LaMothe was elected professor of ophthalmology at a recent meeting of the Board of Directors of the Chicago Eye, Ear, Nose, and Throat College.

Dr. Mary Wolfe has been elected clinical professor of psychiatry in the Women's Medical College of Pennsylvania. She was for seven years chief resident physician to the women's department in the Pennsylvania State Hospital for the Insane at Norristown.

The Seventh Council or District Medical Society of Texas, meeting in Austin recently, elected the following officers: *President*, Dr. W. A. Harper of Austin; *Secretary-Treasurer*, Dr. L. B. Bibb of Austin; *Board of Censors*, Drs. E. M. Thomas of Georgetown, S. E. Hudson of Austin, B. M. Worsham of El Paso, J. C. Anderson of Granger, H. B. Granberry of Austin.

The Placer County (Cal.) Medical Society has elected the following officers for the ensuing year: *President*, Dr. J. G. Mackay of Truckee; *Vice-President*, Dr. G. W. Davis of Lincoln; *Secretary-Treasurer*, Dr. G. H. Fay of Auburn.

The Dorchester County (S. C.) Medical Society, meeting at St. George in December, elected the following officers for 1910: *President*, Dr. Simmons of Summerville; *Vice-President*, Dr. W. P. Shuler of Grover; *Secretary*, Dr. J. B. Johnston of St. George; *Treasurer*, Dr. Elias Tupper of Summerville.

The Bryan County (Okla.) Medical Association has elected the following officers: *President*, Dr. J. L. Shuler of Durant; *Vice-President*, Dr. J. F. Parks of Durant; *Secretary-Treasurer*, Dr. D. Armstrong of Mead.

The Crafton County (N. H.) Medical Society, at its sixth annual meeting held at Woodville, December 14, elected the following officers: *President*, Dr. F. G. Smith of Lebanon; *Vice-President*, Dr. W. E. Lawrence of North Haverhill; *Secretary and Treasurer*, Dr. George G. Weaver of Warren.

The Custer County (Okla.) Medical Society, meeting in Custer, elected the following officers: *President*, Dr. Gordon of Weatherford; *Vice-President*, Dr. Omer of Thomas; *Secretary*, Dr. Parker of Custer; *Censors*, Drs. McBurney and Rogers of Clinton.

Medical Officers of the Militia of Canada.—At a representative meeting of the medical officers of the Canadian militia in military district No. 8, held at St. John, N. B., December 21, a branch of the association of medical officers of the militia of Canada was formed. A constitution was adopted and in the future the annual meeting will be held during the annual camp. The officers elected were as follows: *President*, Major Walker of St. John; *Vice-President*, Capt. Skinner of St. John; *Secretary-Treasurer*, Capt. E. O. Steeves of Moncton.

The Society of Directors of Physical Education in Colleges held a session recently, at Columbia University, at which Dr. Savage formerly of Columbia presented an elaborate study of the injurious effects of the Marathon run and Dr. Meylar of Columbia one on the effect of smoking on college students. The following officers were elected:

President, Prof. Amos Alonzo Stagg, physical director at the University of Chicago; *Vice-President,* Dr. Frederick E. Leonard of Oberlin; *Secretary and Treasurer,* Dr. Paul C. Phillips of Amherst.

The Homeopathic Medical Society of Western Michigan, at a meeting held at Grand Rapids, December 15, elected officers as follows: *President,* Dr. G. L. LaFevre of Muskegon; *Vice-Presidents,* Dr. S. Porter Tuttle of Grand Rapids, Dr. C. D. Mulder of Spring Lake, and Dr. George McCormack of Grand Rapids; *Secretary and Treasurer,* Dr. C. E. Beeman of Grand Rapids.

The Orleans Parish (La.) Medical Society met at New Orleans on December 11, 1909, and elected officers for 1910 as follows: *President,* Dr. B. A. Ledbetter; *Vice-Presidents,* Dr. E. H. Wallet, Dr. L. Thibout, and Dr. C. A. Chavigny; *Secretary,* Dr. Charles T. Holderith; *Treasurer,* Dr. Howard D. King; *Librarian,* Dr. Homer Dupuy; *Board of Directors,* Drs. Joseph T. de Grange, Dr. Arthur Nolte, W. F. Seemann.

The Riverside County (Cal.) Medical Society has elected the following officers for 1910: *President,* Dr. A. W. Walker; *Vice-President,* Dr. H. A. Atwood; *Secretary and Treasurer,* Dr. G. E. Tucker.

The Waldo County (Me.) Medical Association held its annual meeting in Belfast, on December 13, and the following officers were elected: *President,* Dr. A. E. Kilgore of Brooks; *Vice-President,* Dr. E. L. Stevens of Belfast; *Secretary,* Dr. C. M. Whitney of Unity, and *Treasurer,* Dr. O. S. Vickery of Belfast.

The Wells County (Ind.) Medical Society has elected officers for 1910 as follows: *President,* Dr. I. N. Hatfield; *Vice-President,* Dr. A. W. Brown; *Treasurer,* Dr. Leonidas Mason; *Censor,* Dr. J. W. McKinney.

The Williamsburg County (S. C.) Medical Society, at its meeting at Lake City, December 24, elected the following officers for 1910: *President,* Dr. Woods; *Vice-President,* Dr. T. B. Hinnant; *Secretary,* Dr. Kelley; *Treasurer,* Dr. Rollins; *Censors,* Drs. Lynch and Courtney.

The Williamson County (Tex.) Medical Society met at Georgetown, December 9, 1909, and elected officers as follows: *President,* Dr. E. Doak; *Vice-President,* Dr. D. M. Cook; *Secretary,* Dr. C. C. Black; *Censors,* Dr. F. D. Shepherd and Dr. J. H. Petty.

The Shawano County (Wis.) Medical Society has elected its 1910 officers as follows: *President,* Dr. Rothman of Wittenberg; *Vice-President,* Dr. Stubenvoll of Shawano; *Secretary and Treasurer,* Dr. J. B. Gordon.

The South Texas Medical Association has elected officers for the ensuing year as follows: *President,* Dr. William Keiller of Galveston; *Vice-President,* Dr. W. S. Weir of Beaumont; *Secretary-Treasurer,* Dr. E. F. Cooke of Houston.

The Travis County (Tex.) Medical Society, at its annual meeting at Austin, on December 10, elected the following officers for 1910: *President,* Dr. Frank Maxwell of Del Valle; *Vice-President,* Dr. J. W. Gibson of Austin; *Secretary,* Dr. E. M. Dechard; *Censor,* Z. T. Bundy.

Obituary Notes.—Dr. Sarah Read Adamson Dolley of Rochester, N. Y., died at her home, December 27, 1909, aged 81 years. Dr. Dolley was a graduate of the Central Medical College of Syracuse, in 1851, and was the second American woman graduate in medicine. She was a member of Monroe County Medical Society, the Medical Society of the State of New York, and the American Medical Association.

Dr. Henry Holcombe Malone of Brewton, Ala., died at his home, December 19, 1909, aged 73 years. He was a graduate of the New York University Medical College, in 1860, and a member of the Escambia County Medical Society, and of the Medical Association of the State of Alabama.

Dr. Edward L. Perrault of San Francisco died December 17, 1909. He was a graduate of the Cooper Medical College, in 1885, and was a member of the San Francisco County Medical Society, the Medical Society of the State of California, and the American Medical Association.

Dr. George H. Thompson of Belchertown, Mass., died suddenly on December 23, 1909, aged 77 years. He was a graduate of the New York University Medical College, in 1855, and was a member of the Hampshire County and Massachusetts Medical Societies. During the Civil War Dr. Thompson served as surgeon to the Thirty-eighth Massachusetts Regiment.

Dr. George F. Keiper of Pierce, Neb., died in San Diego, Cal., on December 3, 1909, aged 73 years. A graduate of the Rush Medical College, Dr. Kieper retired from practice in 1885 and devoted his time to literature and politics. From 1886 to 1890 he served in the lower house of the Nebraska Legislature and in 1890 was elected State Senator. In 1892 he was the Democratic nominee for Congress but was defeated. He then was appointed Superintendent of the Norfolk Hospital for the Insane.

Dr. William A. Monnish of Atlanta, Ga., died January 2, 1910, in San Francisco. He was a graduate of the Atlanta Medical College in 1890.

Dr. Alfred J. Horowitz of New York died suddenly in Newark, January 1, 1910, aged 28 years. He was a graduate of the Long Island College Hospital.

Dr. Albert Simon died at Reading, Pa., on December 31, at the age of 81 years. He was graduated from the University of Berlin in the year 1849, and he served as a surgeon in the United States Army during the Civil War.

Dr. George A. Weida of Frederick, Pa., died suddenly, on December 30, at the age of 43 years, while engaged in extricating himself, with a horse and sleigh, from a snow drift. He was graduated from New York University Medical College in the class of 1866. He had been twice elected to the State Legislature.

Correspondence.

SPASMODIC CONTRACTION OF THE ESOPHAGUS IN A CHILD, RELIEVED BY GASTROSTOMY.

To the Editor of the Medical Record:

Sir:—In your issue of December 11, 1909, there is an interesting editorial note on "Spasmodic Stricture of the Esophagus in Infants," along with Dr. La Fétra's diagnosis of this condition in a case during life.

I would add the particulars of a boy, Edw. S., aged ten, who was brought to me by his parents from Croton Falls, N. Y., March 26, 1906. They said that he had been vomiting his food after taking it from infancy. Something seemed to collect in his esophagus, and when asleep caused a noise in his throat. Solids he threw up the next day unchanged, and lately even the smallest quantities of liquid

nourishment were hardly disposed of, so that he had become very emaciated. I recommended my colleague, Dr. George E. Brewer of the Roosevelt Hospital, to perform gastrostomy on him so that he could be fed through the opening in the stomach, as he was in immenent danger of dying from starvation. Dr. Brewer was sure that he found an organic stricture at the lower end of the esophagus, from which opinion I disagreed, regarding the contraction as due to a neurosis which might subside if the parts had a complete rest for six months. This proved to be the case, for on November 3 he came, having gained in weight and strength, Dr. Brewer passing a large bougie without hindrance through the formerly contracted part, so that he could afterward be fed in the usual way.

Wm. Hanna Thomson, M.D.
70 East Fifty-fourth Street.

OUR LONDON LETTER.

(From Our Regular Correspondent.)

NEW ENDOWMENTS OF RESEARCH—THE KING'S HOSPITAL FUND —ARMY MEDICAL REPORT—RESEARCH DEFENCE SOCIETY— "LONDON'S MODEL HOSPITAL"—POLYCLINIC'S CONVERSAZIONE —THE LATE SIR ALFRED JONES—OBITUARY.

London, December 17, 1909.

Yesterday came the announcement of a munificent new endowment of medical research which has been made by Mr. Otto Beit in memory of his late brother, Alfred. You will remember that the latter provided in his lifetime a sum of £50,000 to found an Institute of Medical Science, but the scheme fell through and eventually the money reverted to Mr. Otto Beit, as his brother's residuary legatee. To this sum Mr. Otto Beit now adds as much as will make up an amount of £215,000—yielding an income in trustee stocks of about £7,500—to be devoted to the creation of fellowships for the promotion of medical research. Mr. Beit set forth his scheme in a letter to the Senate of the London University, asking, in view of the fact that the researches will mostly be made in institutions allied to the university, its principal for the time being might be one of the trustees. The Senate met on the 15th and the vice-chancellor replied, gratefully accepting the proposal as to the principal joining the board of trustees, and expressing confidence that the scheme will not only perpetuate the memory of Mr. Alfred Beit, but will promote the development of the higher education in the medical sciences and encourage those medical schools he so desired to assist.

The scheme, you will notice, is to be carried out by a body of trustees. As the first board Mr. Otto Beit has associated with himself Lords Milner and Curzon, Drs. Miers and Fowler, and Messrs. Haldane and Bouchier Hawkesley.

The trustees are to be assisted by an advisory board, consisting at first of Sir Clifford Allbutt, Drs. Rose Bradford, Kingston Fowler, C. J. Martin, William Osler, and E. H. Starling.

The fellowships are to be open to any person of European descent, by both parents, without restriction as to nationality, who at the date of election has taken a degree in any faculty of any university in the British Empire approved by the trustees, or, if a female, has passed such an examination as would entitle a male to the degree. In exceptional cases the trustees, on the recommendation of the advisory board, may accept a registrable medical diploma in lieu of a degree. There is no restriction as to age, or religion, or medical opinions. The fellowships are of the annual value of £250, tenable for three years, and the usual number will be ten a year, three months' notice being given by advertisements. The first election will be in March next, when ten will be awarded. In future years the elections will be on or about the first of January.

The list of places of research already recognized is annexed to the scheme. It will suffice to say it includes most of the hospitals, schools, and laboratories connected with the university, and others may be added by the trustees after receiving a report from the advisory board. Fellows must carry on their researches at the place where they have been authorized and can only change it, or the subject of their research, by permission of the trustees, sanctioned by the advisory board, without whose sanction they may not hold any appointment, paid or unpaid, or work for any additional professional examination or degree except such as may be obtained by the presentation of a thesis. They will, in fact, be required to devote all their time to the prosecution of their authorized research.

The Prince of Wales presided on Monday at the meeting of the King's Hospital Fund at Marlborough House and remarked that it was always a pleasure to him to have the meeting in his house, especially when the prosperous state of the fund was a cause of congratulation.

Lord Rothschild reported the amount received for the year as £133,977 5s. 4d. Sir H. Burdett said the League of Mercy would renew its contribution of £19,000, in addition to nearly £2,000 already distributed, on which the Prince expressed the satisfaction of all present, as he knew the extreme difficulty of collecting these small sums. Sir William Church then read the report of the distribution committee, a lengthy document, detailing the awards for the year and discussing several points. These were alluded to in the Prince's speech in moving the adoption, which was duly carried. His Royal Highness said the largest donation of the year was one of £4,775, being half the available surplus of the Franco-British Exhibition. He reported the gratification of the King that the amount for distribution was maintained and added this could not be done without effort. The income from investments is not yet £70,000, and beyond that the fund has only subscriptions and donations, the League of Mercy, and legacies. There has been some diminution of subscriptions, but he hoped it would be only temporary. In three or four cases the committee recommended especially large grants to hospitals in difficulties, and His Royal Highness thought the power of so assisting in exceptional difficulties, after careful inquiries, of the greatest benefit. He then referred to the amalgamations which have been accomplished in two cases and the expectation that a third case will in due course be added. A committee had considered and reported on the question of expenses of charity entertainments. Without laying down regulations, it had been decided to circulate the report, thus hoping to assist hospital authorities and elicit their views as to further action. An inquiry into the out-patient question was postponed pending the issue of the report of the Poor Law Commission, of which much of the evidence is now available, and the Prince expressed a hope that it would be possible to appoint a committee of the fund on this subject in the coming year.

Sir Alfred Keogh is able to report that the decline in the sickness of our army which has taken place during the decade continued in a marked degree during the last year. Between 1899 and 1908 the admission and constantly sick rate figures have been reduced nearly one-half, while the number of deaths and discharges have undergone an equally remarkable change. The number of invalids sent home has also diminished, The saving in hospital accommodation would be difficult to estimate. At the home stations it means 2,000 fewer beds and a similar reduction will no doubt be observed for stations abroad. The results are attributed to changes in medical administration, improved methods of treatment of disease, improved sanitation, and greater care and uniformity in recruiting. The most frequent cause of rejection was the loss or decay of the teeth.

Sir Alfred discusses the dental question at length. He has no doubt that the issue of tooth brushes to the troops and their education in the care of their teeth has been most beneficial. It has prolonged the life of masticatory sufficiency. Our enlisting men are very receptive and it is not more difficult to teach them to clean their teeth than to keep their buttons bright, and once learned the habit is kept up, as it gives them comfort. This was markedly the case in boy recruits in the military schools whose teeth are a bright contrast to other recruits. Improved dental armament is of the greatest value to the soldier, and Sir Alfred looks to early education in the matter to attain it.

A branch of the Research Defense Society has been formed at Brighton. Lord Cromer, president, said everyone who chose to go into the subject could satisfy himself beyond any doubt as to the splendid results achieved. Ample safeguards existed against the infliction of unnecessary pain and if any other measures were needed to secure this or to give greater freedom to experimenters the commission appointed could indicate them.

Sir Conan Doyle maintained that an overpowering case for experiment existed on behalf of animals themselves, putting aside the human needs. Millions of animals were every year saved from anthrax, rabies, rinderpest, and other diseases by means directly due to experiments. Antivivisectionists decried them, but

if their notions prevailed our domestic and other animals would suffer—they are in fact now suffering—from the discouragement of research which had sprung from sensational agitation.

At the fifty-fourth annual dinner of the Poplar Hospital for Accidents, presided over by Sir Hudson Hearley, M.P., chairman of the Port of London Authority, it was stated that 50,000 cases were treated last year, as compared with 20,000 ten years ago. The income had increased from £4,000 to £14,000 and the reserve fund from £8,000 to £50,000. The great feature of this hospital is its close association with the docks, but it serves a wider area. The chairman declared it was London's model hospital; it had ever pursued the sound policy of keeping out of debt and never, like other hospitals, made doleful appeals to the public. Some people, said Sir Hudson, thought that tame policy, but it would always be their policy. It was free. Need was the only passport to its wards and a considerable section of the managers consisted of working men, which, he thought, contributed to the universal confidence felt towards it.

A well-attended conversazione was held at the Polyclinic on the 10th inst. Dr. Bashford gave a demonstration, illustrated by lantern slides, of recent research on cancer. He said the disease was ubiquitous throughout the animal kingdom, and the growth of cancer cells is by the help of the connective tissue, which forms, as it were, a scaffold for the building of the tumor. An emulsion of living skin cells of the same animal previously injected appears to inhibit the help of the connective tissue cells, so that the cancer cells die. Further investigation, it is hoped, will lead to prevention or cure. Meantime, early operation remains the hope of the patient.

Dr. Hampson during the evening showed a number of specimens of radium, radioactive substances, and their actions.

The death of Sir Alfred Jones, on Monday last, is a great loss to Liverpool. As the head of a great shipping firm, he was able to accomplish many philanthropic enterprises, the most important to the profession being the Liverpool School of Tropical Medicine, of which he was founder and first chairman. Under Major Ronald Ross a great work has been done by this school, and much of its success is due to the unsparing help of Sir Alfred Jones, who also seconded the efforts of the Liverpool University, and, indeed, of many other institutions. He visited the tropical dependencies on several occasions and sent out commissions to investigate the diseases. He was deeply interested in the Congo, and, if he could have had his way, would have added it to the British Empire; but the Government opposed this, and it became Belgian. His services to Africa and Jamaica were recognized by the knight commandership of the order of St. Michael and St. George.

Department Inspector-General Horace E. F. Cross, R.N., retired, died on the 13th inst. at the age of sixty. He saw a good deal of active service in South Africa. Previously he was at the bombardment of Alexandria in 1882. He was with the marines in the Soudan in 1884 and present at the actions of El Teb and Tamaai. Dangerously wounded, he was mentioned in dispatches and promoted for these services.

Progress of Medical Science.

Boston Medical and Surgical Journal, December 16 and 23, 1909.

Renal Suppurations in Typhoid Fever.—Seven cases are reported by C. F. Withington, who reviews the literature of the subject and speaks especially of diagnosis of the condition. At what period of the fever is suppuration in the kidneys most apt to occur? In many of the cases of miliary abscess giving no symptom during life the patient died in the third or fourth week and only the autopsy revealed the lesion. But when definite pyelitis existed the clinical symptoms were more marked early in the stage of convalescence, from three to seven days after the subsidence of the fever. In one case the onset was characterized by intense pain in the left lumbar region, with tenderness. The urine was scanty and turbid, with much albumin. The sediment contained epithelial cells, many corpuscles, but no casts. This state of things lasted about eight days, when the picture of a typhoid infection was complete, the first announcement having been made by the pyelitis. The author's personal cases all recovered. If in a given case of typhoid a parenchymatous nephritis develops a largely milk diet is indicated. Urotropin is indicated in all suppurative conditions. Surgical intervention is relatively rarely called for. A closed pyonephrosis calls for operation, a self-opening one does not. Great pain, with lumbar spasm, if occurring with an enlarged kidney, nephrectomy is probably justified.

Treatment of Bacillus Aerogenes Capsulatus Infections by Proximal Injections of Hydrogen Peroxide.—F. F. Lahey details his experimental work. The fact that a normal rabbit when killed and incubated showed *B. acrogenes capsulatus*, reaction indicates that the test for the organism is not reliable, since the same result occurs in noninoculated and inoculated animals. Experiments were also made in a human arm amputated on account of this special infection. The tissues in this arm at the amputation site were pale and edematous, but the *B. aerogenes capsulatus* was not recovered by culture from the wound, so that it would seem that there is a change in the tissue before the organism invades it during the process of extension up an extremity. Smears made from three levels of the wound in the amputated arm show that the purest infection is at the upper part in the direction of extension. The particular organism outstrips nearly all others in rapidity of development. The wound at the middle and lower levels showed a mixed infection. Two of the guinea pigs used in experiments died suddenly after the injection of large amounts of hydrogen peroxide, probably due to the fact that the excess not used up in oxidizing the tissues is taken up by the blood, decomposing it so that emboli may be formed. In all of the animals injected, some living and some dying, it seems beyond any question that the process is localized to the area below the circle of injected peroxide. As a final conclusion the author says that in spite of this the use of the peroxide for this particular variety of infection is in the human being too entirely dangerous to be permissible.

Gastric Ulcer: Subacute Perforation in a Boy of Eight Years; Operation, Recovery.—After some discussion of the statistics of this lesion, with a general description of the condition, F. B. Lund passes on to the description of his own case, which, according to the author, is the only case on record as far as he knows in so young a child. The boy had had several sick spells, with vomiting, but had never raised any blood. One year before coming under observation he had had epigastric pain, with one or two gastric hemorrhages. On admission he was evidently in his third attack of an acute gastric condition. He had sharp pain, vomiting of blood, and some fever. Under observation these symptoms passed off and it was thought he would recover under medical measures. On January 9, 1909, he was discharged from hospital, but was readmitted February 20. Three days later it was felt that in view of his general condition an abdominal incision was justified. Through a median incision just above the umbilicus a large indurated ulcer was found, just to the left of the pyloric opening on the lesser curvature, and firmly adherent to the liver. The adhesions were not disturbed. A posterior gastroenterostomy was performed with a short loop. Recovery was uneventful, save for a short and slight bronchitis. There was no after-history except complete recovery.

Two Cases of "Rusty-Nail" Tetanus with Tetanus Bacilli in the Inguinal Glands.—The cases are reported by C. A. Porter and O. Richardson. Case I. was that of a man of twenty-three years, admitted with the diagnosis of a crushed foot and gangrene of the toes, following an accident occurring a week before. Four days later the temperature had fallen, the wound was cleaning up, and the line of demarcation was evident. During the same night tetanus symptoms came on and the inguinal glands were slightly tender and much enlarged. A four-inch incision was made in the left groin and the anterior crural nerve was injected with a syringe full of antitetanic serum. The wound was drained and loosely sutured. The sciatic nerve was next exposed and filled with serum, the wound being closed without drainage. Finally the bandages were removed from the foot, the toes amputated, the wound curetted and cauterized, and packed with balsam of Peru gauze. Continuation of tetanus symptoms led later to lumbar puncture, withdrawal of two drams of cerebrospinal fluid, and injection of six drams of 25 per cent. solution of magnesium sulphate. He died on the third day, apparently from respiratory failure.

Case II. was that of a boy of thirteen years, who on the thirteenth day after a rusty nail had passed through his foot developed tetanus. He had been under medical care immediately after his accident. Glands in both groins were enlarged, but he had no fever. The left groin was opened and the glands removed. The other surgical measures were as in Case I. Intramuscular injections of serum were given (1,500 units every two hours) and in three weeks the boy left the hospital well. The two cases are reported because as far as the authors know Case II. is the first in which Koch's law has been fulfilled by obtaining a pure culture of tetanus bacilli from a gland and by recovering tetanus bacilli from a rat inoculated with the culture. Should further investigation show that these bacilli are frequently found in the glands a rediscovery of great importance has been made. Experience has shown that the local focus must be eradicated as soon as possible and experience may show that the lymph glands with their lethal bacilli should be removed also. In septic infections the lymph glands act not only as filters, but as active germicidal protectors against a generalized septicemia, and their removal is contraindicated until the region which drains into them has become uninfectious. In tetanus, on the other hand, the local focus can usually be thoroughly disinfected. External drainage is indicated rather than contraindicated. The removal with drainage of the superficial lymph glands infected with tetanus bacilli, so far as can be argued in the light of our present experience, would be of distinct benefit in ridding the organism of a source of toxin production.

New York Medical Journal, December 18 and 25, 1909.

Amebas in the Stools in Pellagrins.—This subject has been studied by W. Allan, whose field of observation has been in North Carolina. His conclusions are, first, that pellagra is often complicated by amebiasis; second, that many varieties of ameba are found in the feces of pellagrins; third, that pellagra is liable to be mistaken for amebiasis and *vice versa*; and fourth, that in diagnosticating and treating pellagra in absence of pathognomonic skin lesions or grave mental symptoms it is first necessary to exclude amebiasis.

What Can We Do to Prevent, Arrest, and Cure Generalized Fibrosis?—An elaborate study of this subject is made by F. S. Mason, who believes that we are on the eve of a better understanding of the whole subject and that we may look for some developments connected with the influence of internal secretions of the parathyroids in connection with generalized fibrosis. Some light may also be thrown on the subject as connected with the injection of certain sera, for he has been much impressed, during his frequent travels in India, by the remarks of some of the physicians there with regard to the effects following the injection of prophylactic serum against the bubonic plague. Such patients appeared to possess a diminished resistance toward other infectious diseases which invariably ended fatally and especially those with an underlying gouty diathesis. In this connection he recalls particularly the case of a personal friend who was gouty and had a long history of alcoholism. He was subject to frequently recurring attacks of true gout and after two injections of the prophylactic plague serum almost immediately developed pulmonary phthisis. Prior to the injection he had pipe stem arteries and a much hypertrophied left ventricle, while after the injections the arteries became soft and he has never had another attack of gout. Of course, this may have been due to failure of compensation and subsequent dilation of the heart, but he mentions this case because he has seen so many similar cases where the injection of this serum has led to patients being carried off by some infectious disease. Is not this change connected with a fibrolytic action of the injected sera?

A Case of Modern "Point Tying."—W. H. Luckett refers to this ancient custom, which originally signified the rendering by enchantment a husband incapable of performing the conjugal rite. Some of the alleged point tyers were anathematized by the ancient church. The author relates two cases which have come under his personal observation in which a fine hair or strand of hairs was tied around the corona glandis. The first patient was an ignorant negro whom a voodoo doctor of the same race had gotten beastly drunk and then appiled the hair, with the result that the penis became gangrenous. The second was a child around whose corona a strand of human hair was applied six times by a neighbor who had a grudge against the child's mother. Severing the hairs was all that was necessary to restore the organ in a short time to its normal condition.

Palliative Treatment for External Hemorrhoids.—G. E. Barnes says that the usual medical treatment of external hemorrhoids by various ointments is often beneficial, but is not satisfactory. Although it is the vehicle for drugs that may have some slight desirable effect and although it mechanically separates the folds and protects them from the air, the grease makes the tissues unduly soft and vulnerable, increases the retention of moisture, and is altogether nasty. The following detailed treatment keeps the tissues in as natural a condition as possible. After every defecation the patient uses only the finest tissue paper and completes the cleaning with a piece of absorbent cotton or a wad of soft cotton cloth or a bunch of crumpled tissue paper thoroughly soaked with water. Soap also should occasionally be used. The tufts and the intervening grooves should be patted and wiped with this mop gently but quite thoroughly. Then a piece of soft cloth or crumpled tissue paper in two or three thicknesses should be repeatedly placed over the anus and pressed with a finger against the whole surface until it is dried. Next a dusting powder made up of talcum and about 10 per cent. of boric acid is thickly dredged on the end of the finger covered with dry cloth or tissue paper and is then applied to the hemorrhoidal area. By this method the surfaces are cleaned and putrefaction avoided, softening of the tissue by retained moisture is prevented, itching is made impossible, and any slight abrasion is healed. After this treatment has been practised for a certain period the delicate mucous membrane becomes more and more like skin.

Cerebrospinal Meningitis: Clinical Observations and Serum Treatment.—L. Fischer refers to the epidemic of this disease in New York City in 1905-1908. The mortality in 1906 was 78.7 per cent.; in 1907, 77.5 per cent.; in the first half of 1908, 71.9 per cent. The absence of sun rays from many of the sleeping rooms of the houses in which the cases occurred was noticeable. Three classes of cases were encountered—a mild type, an abortive type, and a severe type. A positive diagnosis can be made by examining the fluid withdrawn by lumbar puncture. The *Diplococcus intracellularis* is always present. The author describes three typical cases admitted to his hospital service, one dying and two recovering. A decided reaction followed every injection of serum. Pulse rate was increased, volume heightened, and tension considerably raised. Leucocytes were invariably increased with but few exceptions, showing a marked hypoleucocytosis. The polynuclear leucocytes were also increased. As a rule the mononuclear leucocytes and the lymphocytes were reduced within six hours after the injection. Special symptoms noted during the epidemic were convulsions, extreme extension and muscular rigidity, muscular pains, *tâche cerebrale*, various eruptions, the petechial and herpetic types predominating, high fever, and vomiting. The differential diagnosis lies between mastoiditis, severe scarlet fever, particularly of the septic type, and septic pneumonia confined to the pulmonary apices. The paper closes with statistics secured in the recent epidemic. The author says that the mortality of from 60 to 90 per cent. in New York City, during the height of the epidemic in 1906, clearly shows that some better method of treatment than the one in vogue would be welcome. A large number of infants who died were treated by lumbar puncture and intraspinal injections of various drugs; cupping and antispasmodic and sedative treatment; locally, hot baths, in addition to leeches over the spine and mastoid, and icebags have been used with poor result. It remained for Simon Flexner to introduce the antimeningitis serum which has proved of excellent value, and in some instances acted like a specific healing serum in the treatment of this dreaded disease.

Some Interesting Cases of Foreign Bodies Removed from the Ears.—Eight cases are reported by H. Foster of, respectively, screw worms, bit of slate pencil, bead, small stone, grain of wheat, grain of corn, green bug, and lead end of a pencil. All were removed without damage to the organ. In the author's experience it has not been necessary to resort to any cutting operation in removing foreign bodies from the ears. It has required much time and care to effect the desired

result without injury. Much can be accomplished with a good ear syringe and warm water, and these measures should be tried long and well before resorting to cutting operations. Chloroform is the best remedy for parasites.

The Treatment of Tuberculosis by Succinimide of Mercury Injections.—H. Freeman reports four cases and refers to the large number treated in this way by L. B. Wright of the naval service. In the author's cases there was in each one an improvement in the general condition evidenced by increased weight, normalizing of temperature, diminution of cough, expectoration, and night sweats. Each individual case must be closely observed. If the patient is unable to take the full treatment, it is best not to begin. To get the full benefit of this treatment, you must have complete control of the patient and let him and his family so understand it. If the patient has a rise of tempertaure, he should be placed in bed and treated at home until the temperature becomes normal, when he may come to your office for treatment. The buttocks constitute the area for injections, alternating from the right side to the left side. The skin of the area is washed with sterilized hot water or with a piece of absorbent cotton saturated with ether or alcohol; syringe and needle are boiled prior to injections. When the tablet is placed in the barrel the needle is adjusted, ten minims of boiled water are drawn into the barrel, which is shaken to dissolve tablet, when it is ready for use. The needle should be from one inch to an inch and a half in length and should be driven deeply into the muscular tissue by a downward plunge and then the drug slowly injected. If slight hemorrhage takes place by accidentally puncturing a small vessel no harm arises. Give injections every other day, beginning with 0.1 gram and gradually increasing the dose until slight tenderness of the gums or diarrhea is produced; then reduce the dose until these symptoms subside, and continue until thirty injections have been given. After the first series follows a rest of two weeks; then resume and continue as before, or as long as improvement continues. The initial dose of the remedy is about one-fifth of a gram. Indications for reducing the dose are symptoms of approaching mercurialization, sudden rise of temperature, loss of weight, gastric disturbances, excessive cough and expectoration, coming on suddenly, especially when these symptoms have previously been under control.

Trachoma.—The paper of L. J. Goldbach is an exploitation of the so-called "trachoma bodies" as a probable etiological factor. Researches of various authorities along this line are briefly detailed and then follows a description of the author's own experimental work and observations. There is still some scepticism among ophthalmologists regarding the new cause for trachoma. The inoculation experiments of Prowazek, although these do not fulfill Koch's law in that the organism cannot be grown on artificial media, are successful to the degree that the organism is found in 90 per cent. of all cases. Of course, in some conjunctival cases there are changes in form in the epithelial cells, but the typical inclusion of the organism within the cell seems to be characteristic and demonstrable in acute cases of trachoma. In cases that have undergone treatment, this epithelial change and invasion of these bodies are not apparent on microscopical examination. They stain deep violet, and at times with a tint of pink, probably due to the eosin in the solution not being thoroughly mixed. The nucleus of the epithelial cell takes a dark purple, and its protoplasm a light blue. These bodies are usually surrounded by a distinct, clear area. In the epithelial cell they appear as very minute bodies of a regular round structure, smaller than the smallest known coccus. They appear at times conjointly, and again they may assume the form of a diplococcus. In the advanced stages of trachoma without treatment the trachoma bodies are more collected and more intracellular. These trachoma bodies above all should not be mistaken for the eosin stained granules of the leucocytes. It appears that these trachoma bodies undergo a cycle or a transformation. In the very acute cases we usually find grouped in pairs, small, well-stained granulations within the epithelial cell and surrounded by a clear zone; there next appears a cell reaction close to the nucleus; a conglomerate mass results, but still surrounded by the clear zone. This grows larger and usurps the cell protoplasm. In the later stages, when these bodies become more numerous, the clear zone disappears; then follows an invasion of the whole cell and a final rupture of the cell takes place. In this stage the cell is usually well surrounded by leucocytes. In one of the author's cases an intercurrent attack of measles cured the trachoma.

Journal of the American Medical Association, December 25, 1909.

Pus Tubes in the Male.—W. T. Belfield says that these conditions in the male are generally unrecognized, and he defends the use of the name he had given them by describing the clinical anatomy of the parts, showing the analogies with other tubal suppurations. He describes the symptoms, the vesical and rectal tenesmus, the abdominal pain simulating appendicitis, the toxemia causing the neurasthenic symptoms, and the impotence and sterility which are the results. The surgical treatment of these conditions and its advantage over the medical treatment are pointed out. He has operated for draining and medicating the vas ampulla and vesicle 149 times in 107 patients by vasotomy, usually in the office under cocaine anesthesia, and often without assistance, relieving pus tension and offering opportunities for direct medication, also protecting the epididymis from infection, or if infected from pressure infection, as free drainage is afforded through the vas incision. In the technique of vasotomy three features are important: (1) Fixation of the vas, which otherwise may drop into the scrotum; (2) raising the vas through the skin cut for accurate manipulation; (3) exploration of vas for obstruction by sounding with a silkworm thread. When resection is performed a silkworm or catgut thread is passed into the lumen and out through the wall of each cut end and the ends tied above the skin, the thread serving as an axis splint securing exact apposition of the cut end. This method of anastomosis, devised by Mayo, should, he thinks, supersedes all others. His experience has taught him the value of accurate vaccine therapy, especially with autogenous vaccine, as a constitutional aid to the local treatment. He summarizes his paper in the following conclusions: "1. Pus infection of the seminal tract plus occlusion of the ejaculatory duct soon converts vesicle, vas, and finally epididymis into a closed abscess. 2. Vasotomy is the simplest and least objectionable means of evacuating pus, relieving tension, and medicating vas and vesicle. 3. Among the effects of these infections on the urinary organs are bladder irritation and obstruction of the ureter with consequent kidney lesions. 4. Impotence, sterility, and sexual neuroses in the male are frequent results of pus infections of the seminal tract and amenable to appropriate treatment thereof. 5. Vaccine therapy, accurately applied, is the most valuable internal measure against the infections which produce pus tubes in the male."

Facial Tic Douloureux.—L. Pierce Clark and A. S. Taylor report a case of true tic douloureux of the sensory filaments of the facial nerve, cured by extirpation of the geniculate ganglion. The clinical report is by Dr. Clark, who points out that it has recently been proven that the facial nerve, like the trifacial, is a mixed nerve, with its sensory root in the nerve of Wrisberg. He thinks that many of the otalgias will be proved by accurate studies to be due to disorder of this nerve. The operation is described in detail by Dr. Taylor.

Hydrocele.—W. Bartlett suggests as an improvement on the ordinary method of extirpation of hydrocele, the complete extirpation of the sac without opening, to avoid recurrence. A number of text books which he enumerates have been searched for a mention of this method by the author, but without success; nor have any been discovered in the literature by his colleagues who have investigated it for him. The technique is as follows: After turning out the sac in the ordinary way, it is easy to begin its removal at the spermatic cord where the areolar tissue can be readily separated by blunt dissection. The same procedure can be performed over the whole connection between the testicle and the tumor, except at its later reflections from the testis, where some cutting must be done. A number of small blood vessels will have to be ligated. After the testicle has been replaced, metal clips are placed on the wound in the scrotum, close together, covered with powder and no dressing applied. The patient is up and about in four days and no serious postoperative effects have been observed.

Algid Malarial Fever.—T. D. Coleman describes algid malaria, which is one of the three types into which he

divides the pernicious form of malarial disease. He defines this special form as a pernicious type of malaria caused by the estivoautumnal form of the malarial parasite, characterized by profound prostration, cold and clammy skin, and an unclouded intellect; this latter in strong contrast with the comatose variety of the disease. It occurs in all tropical and subtropical countries where malaria is endemic, and does not differ from other forms as to predisposition, age, sex, and race. In subtropical countries it occurs chiefly in late summer or early autumn, as a sequel of more or less chronic malaria. The symptoms are described in detail. The diagnosis is made from the history and the presence or absence of cholera morbus and ptomain poisoning. Of course, the blood examination will be the surest evidence, but it may not exclude coexisting disease. Cases of reasonable doubt, however, are exceptions. The prognosis is generally grave and quinine seems singularly ineffective. He still uses it, however, hypodermically. The rest of the treatment is symptomatic and supportive. Five cases are reported, three of them personal observations, all of which were fatal, as was also one quoted from the literature.

The Deaf Child and the Physician.—J. D. Wright says that we have to deal with three classes of deaf children: (1) Those totally deaf from birth or early infancy, (2) those rendered deaf by accident or disease after speech and some language had been acquired, (3) those partially deaf but with enough hearing to acquire some speech and language through shouting near the ear. The first class must be taught without the aid of the ear. The other two classes must have their speech preserved and improved by careful instruction, and all three must be educated to understand the speech of others by the eye alone or by the eye and ear. A child possessing normal speech even up to eight years of age will lose that speech and become a deaf-mute if hearing is lost and careful attention is not at once given to preserve it. The physician should therefore urge the parents to give the matter their immediate attention, as many doctors have observed that lost hearing may be unrecognized even by the parents. The child should be placed under special trained instruction at not later than six years of age, if well developed and strong it is better to begin at four and a half or five. The deaf child which has not acquired language at the age of twelve has a bitter and discouraging struggle ahead of it. There is still a difference of opinion as to the advisability of the oral or manual methods, but Wright believes that as good instruction can be given by purely oral means as by the other, and it is now used in the majority of cases. He calls attention to several points: "1. The education of the deaf is not a charity any more than the education of your own sons and daughters. 2. All education, and especially the education of the deaf, should be wholly and forever divorced from politics. In too many instances the guidance of institutions for the deaf is entrusted to men of political rather than educational efficiency, and changes in control are made not for the purpose of bettering the school, but for purely political reasons. This is outrageous cruelty to the helpless and dependent child, who innocently suffers for the pride or purse of the politician. 3. The great body of deaf children are bright and normal mentally, and it is unjust to compel the State institutions to include the few abnormal and feeble-minded among the bright ones simply because they are deaf. The feeble-minded deaf should be segregated and taught in schools by themselves as are the hearing feeble-minded. 4. The physician should lend his intelligent aid in placing the deaf child in the school best adapted to his needs."

The Lancet, December 11 and 18, 1909.

The Use of Radium for Local Application Within the Body.—A. C. Jordan says that the three types of radiation are by common acceptance classified as to effect, on the following plan: The gamma rays have a selective action, destroying diseased cells while leaving normal cells intact, while the alpha and soft beta rays are said to have a destroying action, not only on diseased but also on normal cells. To prevent the latter two rays from reaching the body a filter of lead 1 mm. thick is suitable. The gamma radiation appears to consist of ether rays of the same kind as very penetrating rays and in effect the two are comparable. The author has devised the following method for use of radium in the cavities of the mouth, throat, esophagus, rectum, uterus, etc. The radium is in the form of a solution of radium bromide, which is kept in a flask, to which is attached an air pump. The air in the flask is kept partially exhausted and whenever any radium is required the pump is worked till, under the diminished pressure, the solution commences to boil. Radial emanation is carried out with the watery vapor and residual traces of air into the tube leading out of the flask This may be collected in a small length of glass tubing inverted over a cup of mercury and the tubing sealed up in the flame. The original stock solution is never touched. The emanation tube gradually loses its strength. It is possible to draw off daily a radium equivalent to about 40 mgm. of emanation without destroying the value of the stock solution. The latter, however, regains its formal value if this has become diminished, by giving it a few days' rest. Every emanation tube is inclosed in a lead "compo" tube, the ends of the metal being closed down over the glass, rounded off, and sealed up. This tube is put in a tube of rubber, with a long, stout silk ligature attached to one end, and is placed in the various bodily cavities in which it may remain for from twelve to twenty-four hours. Various modifications of the rubber tubes may be made to fit the necessities of each individual case. The advantages of this method over the use of actual crystals of radium are: First, that there is not the risk of losing a valuable crystal tube, and, second, that the crystals may fall down to one end of the tube, whereas the whole length of an emanation tube becomes available. The alpha rays are supposed to be about one hundred times as powerful as the beta and gamma rays together, and if possible should be utilized in therapy. Makower has shown that we have only to expose a negatively charged conductor, for example a wire, to the emanation in order to concentrate the maximum possible quantity of active deposit on its surface. It is thus possible without any difficulty to obtain surfaces whose activity per unit area is enormously greater than can be obtained by any other means. Needles rendered thus active could be inserted into any malignant growths where they would be able to exert all of their energy.

The Rôle of Fats in the Treatment of Disorders of the Stomach.—F. C. Moore and R. L. Ferguson say that the theory of giving fats for their therapeutic action on the stomach is based on the recognition of the frequency with which excessive secretory activity of the gastric glands obtains as a pathological condition and on the demonstration of the depressant action of fats on the activity of normal gastric digestion. The patients on whom the giving of fats was instituted were 26 with gastric ulcer, 3 duodenal ulcer, 3 gastric carcinoma, 4 nervous dyspepsia, 7 atonic dilatation of the stomach, 9 alcoholism, 2 constipation, 8 miscellaneous, 62 in all. Their results are given in tabulated form, in which the HCl content and total acidity are estimated after plain and oil test breakfasts respectively. Whatever the explanation may be, it remains that the neutral liquid fats administered before food lead to a diminution of the subsequent acidity of the stomach contents, the more so the greater the tendency of the secretory activity of the stomach to exceed the normal. Clinically, the authors' experience of the administration of fats, such as cream, butter, almond oil, in conditions in which hyperacidity of the stomach contents has been found to exist, has shown this action of fats to be associated with a very definite amelioration of the subjective manifestations of the condition. In simple forms of hyperacidity depending on slight degrees of digestive hypersecretion (the so-called hyperchlorhydria of Riegel) the addition of cream and butter in abundance to the diet, with a diminution of the starches, will often suffice to remove the subjective manifestations. It is only in the more sever types, and particularly the severe degrees of digestive or continuous hypersecretion so commonly associated with chronic ulcer about the pylorus or duodenum, in which heartburn, acid pyrosis, the sudden gnawing pain in the epigastrium ascribed to pyloric spasm, and the vomiting of acid fluid, that the administration of almond oil is undertaken, and then in doses of one ounce first thing in the morning and repeated before subsequent meals if necessary. This method has proved of value not only in alleviating the symptoms which follow the digestion of food in the stomach, but also in contributing very considerably to the nutrition of the patient, and is certainly preferable to the sole use of alkalies for the purpose of neutralizing the hyperacid stomach

contents and so obtaining relief from the symptom In no case have they found that oil so administered has been badly tolerated or in any way proved objectionable.

Renewed Research on the Subject of Acute Overstraining of the Heart.—Professor Schott of Nauheim describes his own observations, and refers to the work of others, among which he finds great diversity of results regarding the dimensions of the heart in cases of overstraining. First of all, we have to consider that the determination of the cardiac dimensions may have been made under very different conditions. One investigator may have examined during the period of pulmonary inflation; another, after the heart's dilatation had already diminished, while a third may have determined the maximum cardiac extension when the heart muscle was in the condition of greatest relaxation. According to physiological researches of recent years, the heart is constructed in such a manner as to represent the most perfect motor with which we are acquainted, so that it is capable of responding to the smallest stimulus with a maximum development of power. Moreover, it possesses the faculty of adapting itself to changed demands. The dog's heart is capable of taking in six times its normal amount of blood; yet the left ventricle takes in this amount and contracts again completely. Certainly the heart's work increases enormously in overcoming such obstacles, and the increased intracardiac pressure must also be taken into account. But it is a well-known fact that the dog, as far as his heart is concerned, can be subjected, without detriment, to considerably greater and longer hardships than the human organism, although, fortunately, the latter also possesses in its cardiac muscular apparatus and in its vascular system all kinds of temporary compensatory arrangements. To these compensatory powers it is due that the limits of over-expansion of the healthy may lie far apart in the muscularly strong individual. At the same time, we see, nevertheless, that the qualities of the heart manifest themselves, and to these belong laxity and expansion as a consequence of excessive strains.

Pneumonia Migrans.—A case of this nature is reported by H. B. Roderick, the striking features of which were: (1) the cerebral symptoms which persisted through the illness, varying from a semi-comatose state to a violent delirium, (2) the migratory nature of the pneumonia and the small area of lung involved in each attack, (3) the slight disturbance of respiration, which only once reached 40 per minute, being usually about 28, and (4) the rapid recovery after the small dose of antipneumococcic vaccine, which it is reasonable to suppose was instrumental in bringing about the favorable result. The patient was a young woman of 27 years. The duration of active symptoms was 23 days. Recovery was uninterrupted.

Case of X-Ray Ulcers Cured by Hilton's Method.—A. F. Savill reports the case of a woman of 30 years who complained of intense pain in two ulcers situated on the left shoulder and upper arm. They had appeared after prolonged *x*-ray treatment for scleroderma, and the pain was so severe that she had not slept more than one hour at a time for nearly two years. It was decided to follow the Hilton method of dividing the nerves just before they entered the ulcerated area. A semicircular incision was made one inch deep just above the ulcers. Another incision of the same shape, slightly shorter, was made across the middle of each ulcer. Free bleeding was encouraged, the gaping wounds stuffed with antiseptic gauze and fomentation applied. The gauze was left in place for several days, until the subjacent granulations gradually pushed it out of place. The natural healthy discharge was not washed off, but a non-irritant boric acid ointment was laid on. The operation had an immediate beneficial effect, and at the end of a week the patient was able to have a comfortable sleep without any hypnotic. Injections of fibrolysin had been made during her stay in hospital to bring about absorption of the extremely hard sclerodermatous condition of the arm. At the end of three weeks she was completely free from pain, and the ulcers had nearly healed. Complete closure was not effected for several months, and in one of the ulcers a small nodule was particularly obstinate. The method of nerve section was recommended by the late John Hilton in 1863, in his book on "Rest and Pain." He suggested that the pain in obstinate ulcers of various nature was due to exposed nerve endings.

Latent Chorea.—The paper of R. Miller is a contribution to the study of Sydenham's chorea. He considers the condition under the following headings: first, latent chorea associated with acute rheumatism; second, latent chorea in convalescence from acute rheumatism and chorea, and, third, latent chorea without obvious symptoms of rheumatism. He describes the clinical aspect of these varieties and concludes as follows: Rheumatic chorea declares itself first by symptoms significant of general nervous instability. In dealing with children suffering from nervous disorders of many kinds special care should be taken to exclude the possibility of their having originated from slight rheumatic infection. The well-known association between rheumatism and nervous instability is not to be explained by considering that the infection is specially prone to attack neurotic children, but by regarding the nervousness as in most cases the outcome of an infection already present (latent chorea). The mental depression and headache in rheumatic children are usually to be attributed to the disease, and not to its treatment by salicylates. The recognition of latent chorea in children suffering from obvious acute rheumatism affords strong evidence that all chorea is a rheumatic condition.

British Medical Journal, December 11 and 18, 1909.

Calcium Permanganate in Gastritis and Enteritis.—The value of this remedy is extolled by G. A. Stephens, who summarizes five clinical histories of cases in which it was given. The general indications for its use are the same as for bismuth, but the author says that in many cases this drug seems to fail, especially if the enteritis is marked. He prefers to use the calcium permanganate in doses of a quarter of a grain, with plenty of water. The cases reported by the author were of a subacute or chronic type, in which results are better than in the acute type, and he has often noticed that the calcium salts do not act very well when the temperature is raised.

Tetanus Treated with Carbolic Acid Injections: Recovery.—E. M. Phillips reports a case of tetanus occurring in a region in China in which it was not possible to procure antitetanic serum. The patient was a lad of fifteen years. The seat of infection was a small cut on the left middle finger, on the dorsal surface of the proximal interphalangeal joint. The case was seen on the fifteenth day from its onset. Injections were made of 1 cm. of a 4 per cent. solution twice daily. The boy at first improved, but later relapsed. The injections were increased to a 5 per cent. strength and to four times daily. It was deemed unwise, owing to the patient's filthy home surroundings, to give injections of magnesium sulphate into the spine. The boy finally made a complete recovery.

The Treatment of Chlorosis.—C. H. Melland says that anemia in the chlorotic state is due not to a loss of hemoglobin, but to an excess of plasma. Theoretically, therefore, it should be possible to cure chlorosis without the use of iron if only one can diminish the fluid portion of the blood. Consequently, we may use the saline cathartics in connection with caffeine citrate diuretics, theocin sodium acetate with tincture of digitalis, for unless the blood pressure in the glomeruli is maintained, they may be ineffective. The skin may be stimulated by hot packs and hot baths, vapor baths, and by jaborandi. Emesis by zinc sulphate may encourage the loss of water. While these eliminative measures are being carried out, the intake of water must at the same time be limited. As little salt should be taken with the food as possible, so as not to excite thirst. There are many persons who have a sudden edema, but no albumin or casts, so that the condition appears wholly due to a functional inability of the kidney to excrete the normal percentage of sodium chloride, with consequent retention in the tissues and accompanying edema. The patients on this treatment are weighed from time to time, and as excess of fluid is eliminated the weight falls. The improvement under this treatment, however, has in the author's hands been very slow but increased rapidly on the addition of iron to the therapy.

A Personal Investigation into the Dietetic Theories of America.—A. Bruce says that dietetic apostles in America are divided into flesh abstainers, purin-free feeders, and low protein feeders. The theories underlying these three schools apparently meet with little reconciliation. The low-protein feeders admit flesh into their dietary, have not the slightest objections to purins in soup or to xanthins in coffee and tea, and lay no special stress on the observance of other sanitary laws, such as the necessity for exercise, abstention from tobacco, etc. The purin-free school excludes all purins and xanthins from the diet, insist upon at least 50 per cent. more protein, and claim that these are the only practices essential to perfect health. The flesh abstainers agree with the low-protein advocates in the smallness of their protein content, and with the purin-free feed-

ers in their objections to purins and xanthins, but in addition to this expunge every possible toxin from their diet and place the greatest emphasis on the performance of every known law of health. Their chief apostle preaches the necessity of three evacuations of the bowels daily, and for this purpose consumes at each meal liberal quantities of agar—agar in the form of compressed tablets. All three parties agree that most men eat more than is good for them.

Severe Persistent Hemoptysis Checked by Normal Serum Injections into the Veins.—T. W. Dewar was successful by this method after twelve other distinct methods had failed. Twenty c.cm. of normal serum were injected daily for six days, and, apart from their styptic effect, seemed to benefit the patient in every way. On the sixth day a slight rash appeared on the cheek and soon invaded the whole body, appearing, disappearing, and reappearing in a most tantalizing way. It was a mixture of erythema and urticaria. There was also a rash on the buccal mucosa and fauces, great swelling in the pharynx, and evidently some edema of the glottis. His methods to clear his throat resembled a quinsy at its height. His jaws became locked so that nothing could be done locally to relieve his distress. Itching was intolerable, and morphine, atropine, hyoscine, veronal, sulphonal, etc., were all used, but without avail. After these a cup of hot tea at night seemed to afford relief, and he passed better nights. Locally, camphor in hard paraffin succeeded better than lead and opium wash or soda fomentations. The throat gradually improved and there was no desquamation. The day following the disappearance of the rash he had an acute arthritis of the temporomaxillary and wrist joints, and to a slight extent the ankles, with pains in various muscles. This condition was greatly relieved by salicine. Later the rash reappeared for a short time. Serum given by the mouth may fail, but succeed when injected into the veins.

Leukoplakic Vulvitis and Its Relation to Kraurosis Vulva and Carcinoma Vulva.—The paper of Comyns Berkeley and V. Bonney is a description of the first named disease, and the comparison with the latter lesions is accompanied by some excellent illustrations. Leucoplakic vulvitis is defined as a chronic inflammation of unknown origin, characterized in its early stages by marked hyperemia and cellular activity, and in its later phases by marked epithelial hypertrophy and a thickened, sclerosed, and retracted condition of the subepithelial tissue. The main symptom is pruritus, which, in the third stage of the disease, is more or less masked by the pain and acute sensitiveness arising from exposure of the nerve endings. In the latest stage the patient ceases to complain. If, at the third stage, carcinoma supervenes, the ulcers become very painful and tender, bleed easily on being touched, and become hard and indurated in spite of local treatment, and enlarge very rapidly. Kraurosis vulvæ consists of an atrophic condition of the vulva associated clinically with stenosis of the vaginal orifice, and pathologically with certain changes in the dermis. The early appearance of the three conditions named in the title calls for differential diagnosis, and in some instances only the microscopical examination of an excised fragment will render a diagnosis positive. The authors say that with reference to the relief of the pruritus in leucoplakic vulvitis they have had the best results with resinol ointment, zymocide lotion, and the *x*-ray. In view of their pathological findings they advise that in case the remedies named fail, the affected area should in all cases be excised. The excision should be a wide one, lest the disease recur. The treatment for kraurosis vulvæ is to dissect out the painful parts and to enlarge the vulva orifice. In carcinoma the inguinal glands on both sides should be removed whether enlarged or not.

Treatment of Postoperative Shock by Pituitary Extract.—Three cases are reported by G. G. Wray. The preparation used was in a vial, containing 1 c.cm. of a 20 per cent. solution. The contents of one vial were injected into the patient's arm muscles before they had recovered from the anesthetic. The effect was almost immediate, and the barely perceptible pulse soon became large and bounding. This effect lasted from twelve to sixteen hours and then gradually passed off. Not only did the pulse become larger in expansion, but it became also slower, and, whereas it had been irregular, it now became regular. The effect of the remedy seems due not only to its action on the blood vessels, but also to its effect on the heart. The injections were given in connection with normal saline per rectum.

A Simple Method of Counting Leucocytes.—The method is described by V. T. Carruthers, and must be read by those interested. It consists essentially in a thorough mixing of the blood, diluted with water, and so handled that the drops to be counted are of a uniform size. He believes the drops are more uniform than with the Thoma-Zeiss instrument. The materials needed are inexpensive, and the whole method requires only a minimum degree of technical skill.

Is Radium a Cure for Cancer?—Using the word cancer to signify malignant growths in general, L. Wickham says that the malignant evolution of these growths may not only be arrested for months, but occasionally such tumors have entirely disappeared, giving the impression of real cure, the rays having on cancer a somewhat selective action. In cases of large growths there is the necessity of acting rapidly, and the fear from thus acting of causing toxemia. There is no recourse against metastatic growths at a distance. If the cancer is local and accessible, but inoperable, radium can only stop or diminish the secretions and hemorrhages, and occasionaly render the neoplasm operable, but the patient eventually dies of his cancer. The influence of radium lessens as the tumor becomes less and less accessible. Certain tissues are infinitely less affected than others by radium. The mucous membrane of the buccal cavity is especially refractory, and it is difficult to reach the region conveniently and to apply the heavy screen filters and to leave them in position sufficiently long. Lastly, if the cancer is very extensive, a radium therapeutist has great difficulty in obtaining the stock of radium necessary to act sufficiently in every direction, for the number of doses needed in certain cases is very high. Hence, when we speak of curing cancer by radium we are using language not scientific, for we must know and estimate the varying conditions of each individual case. The author is disposed to take a favorable view of the general situation, and he looks for still greater benefits in the future. He believes that the discovery of the remedy has already borne definite fruit in medical practice.

Berliner klinische Wochenschrift, December 6, 1909.

The Gastric Juice in Smokers.—Max Skaller says that the injuries to the human organism from excessive smoking may be direct or indirect, local or by way of the nervous system. Various authors have shown that among chronic smokers there are frequently anomalies of gastric secretions, especially in the form of hypersecretions and hyperacidities. The author, in experiments on dogs, has studied the effect of tobacco upon gastric secretion in order to determine the exact action. The action may be either from the absorption of nicotine from the lungs, or the swallowing of saliva which has taken up the smoke. To simulate the latter the author experimented with water through which the smoke of a cigar or cigarette had been sucked. This water was injected subcutaneously. The first results were those of tobacco poisoning, restlessness, salivation, vomiting, defecation, etc. The gastric secretion in the Pawlow stomach began in from fifteen to forty-five minutes. The latter occurred even when the constitutional symptoms were absent. There was no difference whether the solution was made from the smoke of cigars or cigarettes. In these experiments 20 c.c. of the solution was injected at one time. When this was divided into four doses at fifteen minutes' intervals, no symptoms occurred. In the acid gastritis of smokers the hyperacidity occurs not as a result of but in spite of the gastritis. Cigars from which the nicotine had been extracted gave no hypersecretion. An injection of 0.02 gram of nicotine gave a hypersecretion indistinguishable from that produced by the smoke. These experiments prove that the hypersecretion is an actual symptom of the nicotine poisoning from the smoke. To decide whether the hypersecretion was the result of a direct parenchymatous stimulation of the peptic glands or of the nerves, other experiments were carried out. Atropine was injected prior to the nicotine or tobacco water, in order to paralyze the nerves. The hypersecretion did not occur. This proved that the action was of nervous origin. In the next experiment all the nervous connections of the "small stomach" were severed and the nicotine injected. Here hypersecretion occurred, proving that the nervous stimulation was peripheral, and that the hypersecretion was the result of stimulation of the ganglia in the stomach wall. This supersecretio nicotinica may give no symptoms, or it may give the usual ones of gastric hyperacidity. The therapy of the condition is first prophylactic. This requires complete stopping of the use of tobacco, as in one susceptible to it even a few puffs of a cigarette will produce symptoms. The medicinal treatment consists in giving atropine, 4 drops daily of a solution of 1 to 1,000. The author says that he has never found alkaline medication to be of any service in the severer forms of this condition.

Book Reviews.

MEDICAL JURISPRUDENCE, FORENSIC MEDICINE, AND TOXICOLOGY. By R. A. WITTHAUS, A.M., M.D., Professor of Chemistry, Physics, and Toxicology in Cornell University, and TRACY C. BECKER, A.B., LL.B., Counsellor at Law, Professor of Criminal Law and Medical Jurisprudence in the University of Buffalo; with the collaboration of AUGUST BECKER, ESQ.; A. L. BECKER, ESQ., CHAS. A. BOSTON, ESQ.; Hon. GOODWIN BROWN; W. N. BULLARD, M.D.; G. C. CAMERON, M. D.; J. CLIFTON EDGAR, M. D.; JAS. EWING, M. D.; E. D. FISHER, M. D.; A. S. GEYSER, M.D.; J. C. JOHNSON, M.D.; D. S. LAMB, M.D.; H. P. LOOMIS, M.D.; W. B. OUTTEN, M.D.; ROSWELL PARK, M.D.; J. PARMENTER, M.D.; IRVING C. ROSSE, M.D.; E. V. STODDARD, M.D.; GEORGE WOOLSEY, M.D.; J. H. WOODWARD, M.D. Second Edition, Vol. 3. New York: William Wood & Company, 1909.

THIS new edition of the third volume of Witthaus and Becker's great work contains nearly 250 pages more than the same volume of the first edition. Woodward's article on the "Medicolegal Relations of Vision and Audition" and of "Injuries to the Eye and Ear" remains practically unchanged. A. L. Becker's article on the "Medicolegal Relations of Insurance" is a new one, replacing the old one by Murray and Edwards. Becker's article is shorter, but of more practical value to the physician. Fisher's chapter on the "Medical Aspects of Insanity" remains almost unchanged. T. C. Becker's chapter on "Mental Unsoundness in Its Legal Relations" has been much enlarged, and in some parts entirely rewritten, and it now stands as the work of Becker and Boston. Brown's chapter on the "Care and Custody of Incompetent Persons and Their Estates" has been revised by A. L. Becker. These last three articles, occupying over 600 pages, make a very complete and valuable treatise on the subject in question. A. L. Becker contributes a new chapter on the "Medicolegal Aspect of Marriage and Divorce." This is followed by another new chapter, that on the "Medicolegal Relations of *X*-rays and Skiagraphs," by A. G. Geyser. Ewing's contribution on the "Medicolegal Examination of the Blood and Other Stains and of the Hair" replaces the articles on the same subjects by E. S. Wood; these were in volume two in the former edition. There is a table of cases cited in the volume; this takes up fifty pages of double columns, and constitutes one of the valuable features of the work; to the legal reader it is simply indispensable. The volume concludes with a complete index to the three volumes which comprise that part of the work which deals with medical jurisprudence and forensic medicine.

This work is by far the most complete treatise on medicolegal science in the English language, and every article in it is written either by an expert or by one who has made a special study of the subject on which he writes. The result is that we have here a work which is both authoritative and complete.

UEBER ASTHMA UND SEINE BEHANDLUNG. Von Dr. M. SAENGER, in Magdeburg. Berlin: Verlag von S. Karger, 1909.

THIS is a booklet of seventy pages, in which the author attempts to prove that asthma is a peculiar form of "traumatic neurosis," occurring in individuals predisposed to the affection by peculiarities of their lungs and bronchi. In consequence, the treatment proposed by him depends more upon suggestion and psychic influence than upon the use of drugs. In addition, he has found that a permanent cure may be obtained by training the patients to breathe properly by counting aloud while the lungs are in the expiratory phase. Full details and a number of clinical histories are given by the author.

THE PRINCIPLES OF BACTERIOLOGY. A Practical Manual for Students and Physicians. By A. C. ABBOTT, M.D., Professor of Hygiene and Bacteriology and Director of the Laboratory of Hygiene, University of Pennsylvania. Eighth edition, thoroughly revised. With 100 illustrations, 26 of which are colored. Philadelphia and New York: Lea & Febiger, 1909.

For beginners in bacteriology, Abbott's book has long been recognized as a safe guide. In this new edition the article on infection and immunity has been practically rewritten, and the recent work in protective vaccination and the preparation of antisera has been noticed. Some of the contents of former editions has been eliminated in recognition of recent developments of the science; so that, in spite of valuable additions, the book still retains its former modest size. In another edition the author should insert the explanatory diagrams usually given in connection with Ehrlich's hypothesis, as their omission makes more difficult the understanding of a complex subject.

THEORIE UND PRAXIS DER EISENTHERAPIE, nach dem gegenwärtigen Stande der Wissenschaft. Von Dr. HANS SCHIROKAUER, Assistent am Klg. medizinisch-poliklinischen Institut der Universität Berlin. Halle: Carl Marhold Verlagsbuchhandlung, 1909.

THE use of iron in anemia dates back to the earliest period of medicine, and yet opinions are still discordant as to the best preparations for medicinal use. Much experimental work has been done on the absorption of iron, and it is now practically established that internal administration of this substance causes no increase in the excretion of iron in the urine, but that it is excreted after absorption from the large intestine and is passed in the feces. The daily quantity to be administered in order to obtain satisfactory results is, according to the writer, at least one and a half grains per day. Tables are given to show that many of the recent synthetic iron compounds contain actually very little iron, so that very much larger quantities must be administered than are permissible from the point of view of digestion or of expense. The tendency is to return to the old mixtures, such as Blaud's pills and the tincture of the chloride of iron. It is important that the treatment be continued with great regularity for a considerable period in order to obtain the best results.

DESZENDENZ UND PATHOLOGIE. Vergleichend-Biologische Studien und Gedanken. Von D. von HANSEMANN. Berlin: Hirschwald, 1909.

THE centenary of the birth of Charles Darwin has awakened a new interest in the problem of heredity and a revival of criticism of the ideas which he did so much to make a part of our intellectual attitude toward all biological problems. Von Hansemann, already widely known as a pathologist, has written this volume on the relation between descent and pathology as a contribution to a special phase of the Darwinian theory which has been but slightly touched upon by other writers. He holds that cellular pathology, and especially the study of the hereditary relations of tumors and disease may be of importance in extending the Darwinian concepts. The acquired, though somewhat relative, immunity of man to certain hereditary diseases, such as syphilis, may also be of importance in the modification of type which must be going on in the human race. The variability of the upper thoracic bony skeleton and that of the appendix are cited as examples of such mutations. The theory of altruism, which the author has transferred to the relations between cell types and organs, is also, he considers an important factor for variation. Any alteration in the altruistic cell equilibrium leads to important changes in the organism. Regeneration of tissue may also be considered as an altruistic phenomenon which tends to restore the vital equilibrium and thus preserve the type. If such cellular equilibrium be interfered with, the body substitutes another variety of cell, and selection then may lead to a definite suppression of the original tissues. The physiological death of certain tissues, such as the specific cells of the sexual organs, when the functional activity is no longer required for the existence of the body, may also be a factor in the production of variations. In the Lamarckian doctrine of the inheritance of acquired characters our author has but little faith. The book forms an interesting and suggestive contribution to the evolutionary doctrine.

HOUSEHOLD PESTS AND HOUSEHOLD REMEDIES. By W. R. BOELTER, Author of "The Rat Problem"; "A World's War Against the Rat"; "A Lesson in Economic Zoology," etc. With 86 illustrations. London: John Bale, Sons & Danielsson, Ltd., 1909.

ALTHOUGH the problem in this country in regard to household pests may not be as great as in some others, yet we are not immune. The rôle that vermin play in the spread of disease is becoming more thoroughly understood every year. But the economic loss caused by them is a great deal larger than any of us appreciates. The author estimates that the economic losses in Great Britain alone aggregate annually £100,000,000. "At least 75 per cent. of that huge loss is preventable." The book is divided into fourteen chapters. Each chapter deals with a different variety of vermin, and the remedies to be used for their destruction. The important chapters are those on ants, bugs, cockroaches, flies, mosquitos, mice, and rats. The aim of the author is to influence the people and the English Government to take concerted action and make a systematic war on all vermin.

Society Reports.

THE MEDICAL ASSOCIATION OF THE GREATER CITY OF NEW YORK.

Stated Meeting, November 15, 1909.

THE VICE-PRESIDENT, DR. RANSFORD E. VAN GIESON, IN THE CHAIR.

Private Nurses and Nursing, with Recommendations for Their Betterment.—Dr. THOMAS E. SATTERTHWAITE, in this paper, said that those who had been in practice, as he had, for upward of forty years, and had brought in contact with nurses, in and out of hospitals, of almost every kind, during that time, would realize that the modern nurse was the result of a gradual evolution. After paying a high tribute to the nurses who entered the field for the love of the work itself, and who served as exemplars of a heroism and self-sacrifice that had lifted them up high above ordinary mortals, the speaker referred to the fact that we had reached a period when we could see imperfections in our system, and that all nurses did not measure up the standards we required as physicians and surgeons. He would go further and say that a decided reaction against present methods, originating some years back, had developed, and that it was spreading over the country. The changes he had to suggest in the present system would not only benefit patients and physicians, but would put the art of nursing on a higher level. The first move in the direction of the right sort of reform was seen in England in 1887, when an effort was made to have a Public Bureau for the registration of nurses. Conflicting interests had hindered the movement, but now a Registration Bill had passed the House of Lords and was before the Commons, while at least twenty-three of our States already had registration laws. The United States Government, in 1906, by establishing the Army Nurse Corps, not only provided for the registration of nurses that had passed the required examinations, but also for supervising them. The present New York State law, by not expressing in it the relations of the nurse to the physician, and by permitting registration and examination by a board composed of female nurses, had gone far toward erecting nursing into a profession like that of medicine, and controlled by women nurses. There was no classification according to qualifications and no scheme for supervision. More than this, on the Nurse Training School Council there was but one physician. What we needed was something more than simply State registration after examination. Nurses should be examined by the Board of Regents, classified, supervised, and controlled. If such a plan as this was carried out, it would mean that the physician and surgeon would have better results in their private practice, while the registered nurse would have a higher standing in the community. Every training school for nurses, general or special, should have a certain number of its best nurses free for persons of moderate means and even for charity cases. While the price for trained nurses was not too high for well-to-do people, it was much too high for others. Each up-to-date training school should have an endowment fund with which to furnish those of limited means with the same grade of nurses as of doctors, and all registered nurses should be compelled to take such cases in the order in which they might be called. We also need a better classification of nurses as to their special qualifications, which should be matters of public record.

The Present Status of the United States Army Nurse Corps.—By Major CHARLES LYNCH, M.D., of Washington, D. C., representing the Surgeon-General of the U. S. Army. The speaker said that the Army Nurse Corps did not exist prior to the Spanish-American war in 1898. Early in that war, however, it was found that women nurses were essential for the army, and this led to their employment under contract. This method of employing nurses was regarded merely as a temporary expedient to meet a crying need, and the law organizing the Army Nurse Corps was not finally passed and approved until February 2, 1901. Subsequently, the number of nurses in active service, including chief nurses, but not the superintendent of the Corps, was fixed at 100 by the Secretary of War. Since that time this number has never been exceeded and the present strength of the Army Nurse Corps was 93. Since the American Red Cross had taken up the subject of reserve nurses for the army, who could be called upon in time of war, it had not been thought necessary to build up a reserve in the army itself. Under the present law, the pay of nurses and of reserve nurses when on active service was $40 per month when on duty in the United States, and $50 per month when without the limits of the United States, with an allowance for rations. It had been realized for some time, Major Lynch said, that the attractions offered to induce nurses to enter the active list of the Army Nurse Corps were insufficient to obtain the best class of women from the best schools, and a tentative bill had been drawn up under which the pay of the nurses in the United States would be increased from $40 to $50 per month during the first five years of active service; it would be further increased to $55 during the second five years, to $60 per month during the third five years, and to $65 per month after fifteen years of service. The nurses under this proposed law would receive $10 additional per month when without the limits of the United States, which was the increase at present given for foreign service. Chief nurses would receive up to a maximum of $35 additional to the pay mentioned for nurses. As allowances, fuel and light had been added, although, as a matter of fact, they were not furnished. A provision had also been made for the laundry of nurses' uniforms, and the allowance for ration was to be increased from 30 to 75 cents per day.

A Successful Experiment in Educating Efficient Nurses for Persons of Moderate Income.—Dr. WILLIAM O. STILLMAN of Albany, N. Y., said that if one considered all the practical aspects of the nursing question, few physicians would deny the proposition that there was an urgent need for two classes of nurses. One must necessarily be the hospital graduate nurse, whose services were especially essential in the higher grades of surgical work, and in steady demand in medical cases for such families as could afford the expense. We could not question the great value of her skilled assistance, but we needed another class of nurses who could meet the requirements and the purses of the masses of the people of moderate means. Various attempts had been made to meet this need. The speaker said that he had been deeply interested in this question for the last fifteen years, and for about four years and a half he had been conducting what might be called an "experiment station" for solving the problem of nurses for general domestic service. His work had been in the direction of producing less thoroughly trained nurses, who could afford to work at relatively much lower prices than the registered nurse. Assisted by about a score of physicians and surgeons in the city of Albany, he undertook to start a school for educating and training domestic nurses. The outgrowth of this effort had been the development of a course of instruction extending over six months. Four months of this time were devoted to class work, including lectures by physicians and by the superintendent, who was a registered nurse. Practical demonstrations of nursing technique were given by the superintendent and her assistants; instruction was also given by means of the human skeleton and animal dissections, as well as by the use of charts, etc. It also embraced a fairly thorough course of diet kitchen instruction in preparing food for the

sick. After the academic course the pupil was required to demonstrate her application of the principles taught by two months of bedside work under the observation of the head nurses. The requirements for admission to the school did not include a high-school certificate, but only a grammar school education, and women were not allowed to receive a certificate until they were 21 years of age. Thus far, over 150 pupils had been graduated, and the great majority of these were doing exceedingly well. The graduates were encouraged to restrict their charges to from $12 to $15 per week, and, as a rule, they were in steady demand.

An International Educational Standard for Nurses.—By Mrs. Hunter Robb, late Superintendent of Nurses and Principal of the Training School for Nurses at Johns Hopkins University Hospital. In Mrs. Robb's absence, this paper was read by Dr. Gallant. The writer said it was deplorable to find that as modern nursing was being adopted by first one country and then another, it had to be started in a more or less haphazard way, instead of being able to adopt from the very beginning a common standard and common ideas. It had become an accepted maxim that in the proper education and practical training of the nurse lay in the main the patient's best welfare. She wished to lay special emphasis upon the words practical training, for in them lay the true definition of an educational standard. The word education had little significance unless combined with the three all-important words *proper practical training*. There could be no question but that nursing in itself was an art that should admit of only one way of caring for sick people—the right way—not a half a dozen right ways, not one peculiar to Great Britain, Germany, America, or any other country, but the right way for all, and to actually find this right way and put it into daily and hourly practice the world over should be at the very basis of all our nursing organizations, and should be the fundamental reason for their existence. Nursing was an art that should be practically the same all the world over; in its practice it was without creed or country, governed by the same law for rich and poor, and for all alike its motto was the Golden Rule. Nursing work should be and was second to none done by women, and no stone should be left unturned to place a true and proper value upon it and help it reach its highest level. In a broad general way, the meetings of the International Council for Nurses have been of the greatest value. It was an inspiration and source of encouragement to know that other countries were facing this same problem, working toward the same common standard, which the writer said she felt convinced would be realized much more rapidly did we concentrate our attention a little more upon the methods employed in the actual making of the nurses, and did we unanimously insist upon rendering universal a thorough practical training, which would supply a standard that should be the ultimate outcome of the combined wisdom, experience, and deliberations of the nurses of all countries where modern nursing existed.

Mr. George P. Ludlam, Superintendent-Emeritus of the New York Hospital, said he had rarely listened to a series of papers on this subject that had been more comprehensive and covered the ground more completely and conclusively than those that had been presented. The only suggestion he had to offer in connection with the proposed law outlined in Major Lynch's paper was that it contained no provision for a pension for nurses who had worn themselves out in the service. The paper of Dr. Stillman was full of interest and instruction, and his successful experiment in educating efficient nurses for persons of moderate income was worthy of imitation of other communities. He could not comprehend, however, how the nurses covered the work that was laid out for them in a six months' course of study, and he did not believe that some of the things that were included in the curriculum were wholly necessary; in fact, he thought they might be rendered more efficient practical nurses by curtailing it. Dr. Satterthwaite's paper had impressed him with the fact of the different point of view that prevailed on this subject among physicians from that of layman—or rather, the more comprehensive view held by the former, embracing, as it did, the nurse's professional relations and also her conduct in the social and domestic environment in which she was placed. In his long experience in hospital work, Mr. Ludlam said he had listened to a great many complaints of employers about the conduct of nurses, and *vice versa*, and, as a rule his sympathies had been with the nurses. It was undoubtedly true that many members of the community regarded the advent of a private nurse in the family very much as they would the occurrence of an earthquake or a cyclone, although there were not many nurses who conducted themselves so as to justify that comparison. Still, it could be safely said that the sentiment in the community at large was one of regret whenever, in any family, the necessity arose for employing the services of a trained nurse. He would look for the cause of this feeling of unrest against the trained-nursing system in the kind of education which the pupils received in the average training school. He did not mean so much over-education or an overcrowded curriculum, but rather what was perhaps the outgrowth of instilling false notions into the minds of the pupils. Under the present system, the nurse received the idea that she was a member of a profession and she expected to make it a profession by calling it so, and thus she was sent out into the world with distorted and exaggerated notions of her own importance, a tendency which the speaker said he honestly believed tended to eliminate or subordinate those eminent traits of character, of tenderness and sympathy and prompt attention to the wants of the sick which should form the very substratum of her work, and which had been so admirably presented in the paper of Mrs. Robb. Under the present system, the trained nurse was led to regard the sick person too much as a "case" instead of as a human being in need of the care and sympathy which she could give. In closing his remarks, Mr. Ludlam said he did not wish to be understood as posing as an enemy of the trained nurse or the trained nursing system, but he found in both some things that seemed to invite criticism.

Dr. Arpad G. Gerster said that while he had been much interested in the papers that had been presented, he thought that Mr. Ludlam, in discussing them, had touched the main spring of the whole question closer and nearer and with much more precision than did the papers themselves. The work of the training schools in this country and the work of the nurses themselves had been put on a false basis by an influence which might be called partisan and feministic. We should not look upon nursing as the exclusive work of women, and only that system of nursing could be regarded as entirely satisfactory that could be equally applied to the education of both male and female nurses. The principles should be absolutely the same for both sexes. On the other hand, we must admit that the whole question was still a recent one; it was still *in statu nascenti*, as the chemists say. It was natural that certain differences of opinion should develop among those who in their work of training the nurses were influenced by temperament or by the particular views of this or that educator. One teacher laid great stress on the practical side of the teaching, whereas another laid enormous stress upon the theoretical side. Personally, Dr. Gerster said, he believed that the tendency to crowd the brains of nurses with a great deal of theoretical knowledge, digested or undigested, had taken such a strong hold upon those who controlled the training schools in this State that it was open to criticism. He had looked over the papers that had been issued in Albany for the examination of nurses for State registration, and had found therein many questions that could not, in his comprehension, be either useful or neces-

sary to the proper training of nurses. For example, one of these questions was, "What is meant by immunity?" Others, just as useless, could be selected from the list at random. While a certain amount of theoretical knowledge was doubtless useful and even necessary in the curriculum of the training school, it should not be carried to a degree that was burdensome to the already overworked students, and it was upon this very point that there was still much difference of opinion. Personally, he believed that this amount of theoretical teaching should be reduced to a minimum; he regained it as a shibboleth and false god which should be thrown from its pedestal, and which created in the minds of the nurses themselves false standards and a feeling of superiority which had no basis in fact.

Dr. W. Gilman Thompson said that if the medical profession did not get the kind of nursing they wanted, it was absolutely their own fault. They had allowed to grow up in this country a large nursing "trust" which controlled prices and restrained trained attendants from acquiring hospital experience. In 1883, the speaker said, he wrote a small book on Training Schools for Nurses, and give a brief account of the twenty-two schools then in existence. In 1908 there were 935 such schools, and their graduates were increasing at the rate of 500 per year. During the past decade there has been an average of forty-two new schools established yearly or almost one new school per week. The amount of capital more or less directly interested in these enterprises he had conservatively estimated at ten millions of dollars. In New York City there was one municipal training school building that cost $700,000 and a second one that cost $350,000. These figures gave an idea of the magnitude to which this industry had grown. There was only one grade of diploma among the graduates of training schools and a standard price for their services, whether good or poor. This applied to no other vocation to the same degree. It would be a simple matter, Dr. Thompson said, for the schools to issue two kinds of diplomas, one, say, for two years' service and another *cum laude* for advanced work for those who wished to perfect themselves in certain specialties. Nurses had recently paid much attention to legislation, and there were at least six different kinds of laws governing the registration of trained nurses in different States—almost as many as there were divorce laws. If we classified the nurses, the question of their remuneration would then take care of itself. As it was, it was impossible for a trained attendant to get any hospital experience. If this permission could be obtained, to meet the public demand, a large number of women could be admitted to hospitals as trained attendants, and receive a diploma or certificate at the end of six or eight months or a year, just as short term certificates were issued to hospital internes. There were two fundamental things that it was important for nurses to learn, one, the principles of antisepsis in surgical cases, and the other, how to make patients comfortable in bed.

Dr. C. Irving Fisher, Superintendent of the Presbyterian Hospital, said that his experience with nurses had been practically confined to their work in the hospital. The entire subject was still in its developing stage, and many problems pertaining to it were still being worked out. He did not believe that the establishment of a central bureau for discovering and eliminating bad nurses, as suggested by Dr. Satterthwaite, would prove an absolute cure for the shortcomings of the present system. Their correction, rather, lay in the hands of the training schools themselves. Among the graduates of every training school, as of every medical school, there were a certain proportion who had utterly failed to imbibe the spirit of their teaching and who were sent out into the world unfit for their work. Still, in the course of time, such matters adjusted themselves. Good nurses, like good physicians, would make a success of their calling, while those who were unfit or who lacked the proper spirit would fail and drop out.

Dr. Otto Kiliani said that for the past ten years he had been one of the teachers in the training school for nurses at the German Hospital, and Chairman of the Nurses' Committee, so that he was naturally deeply interested in this subject. He agreed with Dr. Stillman that we were in need of a class of nurses whose services could be engaged by persons of average means. As it was at present, only the extremely rich and the extremely poor were well taken care of. Under the present system, the nurse who had taken a three-years course of study could not be expected to work for less than she now asked, which did not average more than $750 per year. In the training school connected with the German Hospital they were now considering a plan by which persons in the city of New York, at least in moderate circumstances, could be furnished with nurses at a price that would be within their means. During the last six months of the three-years course of study it was intended to send the nurses out to do practical nursing in the families of patients who could pay, according to their means, $5, $10 or $15 per week. This money would not go to the nurse, but to the hospital to help meet the expenses of this special branch. The nurse would be expected to go wherever she was sent, and this would be regarded as a part of her regular course, and at the same time she would be benefited by coming in contact with private patients. In closing his remarks, Dr. Kiliani said he regarded the present three-years course for nurses as too long, and he deprecated the efforts that were now being made to raise the preliminary standard of education for those who wished to enter the training schools. This standard seemed to be high enough now and it was questionable if any of the larger hospitals and their training schools desired any raising of this standard.

Dr. J. Blake White said that while no one, more than he, appreciated to a greater degree the character and efficiency of the conscientious nurse, he would not be true to his own observations nor true to the nurses constituting the type nearest to the ideal nurse if he did not acknowledge that there were some who were not as they should be or what was expected of them. There was no doubt we could not very well get along without nurses—even the less efficient or less faithful nurse did some good—but to be most useful in her profession she must not only serve her patient faithfully and well, but she must never lose sight of her obligation of loyalty to the physician who under under all circumstances bore the burden of responsibility of the case in hand. The simple matter of educating a nurse did not, in the speaker's opinion, fully fit her for her work, which was a multiple requirement. She might be trained as to her head and her hands, but the best of her efficiency came from her heart, whence emanated those personal qualities impossible to define, but which no training or education could supply.

Dr. A. Ernest Gallant thought that the question of nursing among the poor should be taken up by the churches, and he referred to the excellent work now being done along those lines by the visiting deaconesses among the Baptists and Methodists, and by the Sisters of Charity of the Catholic church.

The discussion was then closed by Drs. Satterthwaite and Stillman, and Major Lynch.

Olive Oil in Hyperchlorhydria.—The part played by the gastric mucous is that of protecting the walls of the stomach against attack by the gastric juice. Schalij, when the secretion of mucus is arrested, gives olive oil and almond oil. The oil is taken neat before meals, beginning with a dose of 1 c.c. (mxvij) and increasing by degrees to 15 c.c. (ʒss.). The treatment has the additional advantage of decreasing the acidity of the contents of the stomach.—*Archives des maladies de l'appareil digestif.*

NEW YORK ACADEMY OF MEDICINE.

SECTION ON PEDIATRICS.

Stated Meeting, Held December 9, 1909.

DR. ELI LONG IN THE CHAIR.

Amaurotic Family Idiocy.—Dr. ISIDORE GOLDSTEIN presented three cases of amaurotic family idiocy.

CASE I.—This patient was a female, born of semitic parents, and one year of age. The family history was negative. When six months old the child could sit and raise herself from the supine to the sitting position. Shortly after this the mother noticed that the child could not hold her head up, sit, or hold firmly any object given her. She was constipated. She laughed aloud without apparent cause, and was easily frightened. The tongue protruded. The hands were closed most of the time. The anterior fontanelle was almost closed. The child had a vacant and silly look. There were irregular twitchings of the facial muscles. There was a tendency to turn the eyes upwards. The pupils were normal. The fundi showed the characteristic grayish-white patch in the macular region; in its center was a brownish-red, sharply defined oval spot. There was optic atrophy. There were chewing movements of the mouth, smacking of the lips, and saliva escaped from between the lips. The arms were held outstretched and stiff. The tips of the thumbs and index fingers were in contact. The reflexes were exaggerated. There was no Kernig, Babinski, or Oppenheim sign. The Wassermann reaction in both mother and child was negative.

CASE II.—This patient was a female, sixteen months old, of Jewish parentage. She was the tenth child and three of them were amaurotic, one being a twin. The family history was negative. The child was never able to sit or stand without support; she was easily frightened, did not recognize her parents, and had difficulty in swallowing. She once was very fat, but now was growing thin and weak. The anterior fontanelle was closed. The fundi showed the characteristic spots. The child was stupid, with a vacant, listless expression. There were chewing movements. The upper and lower extremities were spastic. The reflexes were exaggerated. There was no Kernig or Babinski sign. The Wassermann reaction was negative in both mother and child.

CASE III.—This patient was fourteen months old, the second child of Jewish parents. The family history was negative except for a history of consanguinity in mother and father. The duration of illness was ten months. The child could not sit, was hardly able to support the head, and did not stand or walk. The child cried a great deal, and laughed without apparent cause. The anterior fontanelle was open and pulsating. The fundi showed the characteristic spots, and optic atrophy was present. The saliva dribbled from between the lips, and there were chewing movements. The forearms were markedly flexed, and the tips of the thumb and index fingers were in contact. The reflexes were exaggerated.

Congenital Muscular Dystrophy.—Dr. KAUFMAN SCHLIVEK presented this case. The patient was a female, two years and three months old. The family history was negative. The child had never been able to flex the elbows or the knees, and the feet were always turned in. The child did not move the arms until she was six months old; then she began to raise them slightly. The legs were moved from birth. She could stand with support. She was bright and well nourished. There were no signs of rickets. The upper extremities were held in the position seen in Erb's paralysis, complete extension at the elbows, and rotated inwards. The anterior part of the arm was flat, soft, and flabby. The anterior surface of the humerus was readily felt. The shoulders were fairly well developed, as were the forearms. The child could raise the right arm to almost 90° and the left a little higher. Active and passive motion of the right elbow was limited to 30°, the left elbow to 60°. Pronation and supination of the forearms were good. The motion of the fingers, hands, and wrists were normal. The muscles of the thigh and legs were soft and flabby. Flexion at the knees was limited to 45°. There was marked lateral motion in the knees, but no creaking. The feet were in the position of talipes equinus varus. The back muscles were well developed. The entire skeleton had been subjected to the *x*-rays and the only condition worthy of note was that the articular surfaces of the elbows and knees were in closer proximity than normal. The bones of the ankle were undeveloped. The mental condition of the child was excellent. There were no trophic disturbances, the sensations were normal, and there was no reaction of degeneration.

Dr. HENRY W. FRAUENTHAL believed that the range of motion could be increased if massage and manipulation were properly employed.

Dr. ALFRED F. HESS did not think that the diagnosis was at all clear. The muscles appeared to be in good condition. The *x*-ray showed the articular surfaces of the bones close together. The pathological condition was a partial or complete absence of interarticular cartilage; sometimes there was an exostosis of the bones. This was in fact a well-defined condition and was not always hereditary. It was a separate disease and should not be classed with the dystrophies.

Dr. Schlivek said that the only way to make an absolutely positive diagnosis of the case he presented was to take a section of the muscle, which, of course, was prohibitive. There was no limitation of passive motion at the shoulder; this joint was normal, and still the child could not raise the arm above 90°. From this demonstration they must infer that there was muscular weakness. Last spring the patient was shown at Dr. A. Jacobi's home and a tentative diagnosis was made of congenital muscular dystrophy. Dr George W. Jacoby confirmed this diagnosis.

A Case of Cerebral Hemorrhage.—Dr. HENRY W FRAUENTHAL presented a young boy who had had a cerebral hemorrhage, leaving the face, arm, and leg partially paralyzed.

Protective Action of the Colloids in Milk, with Some Ultramicroscopic Observations.—JEROME ALEXANDER, M.Sc., and Dr. JESSE G. M. BULLOWA presented this paper. If one examined the suspension of any fine powder with the microscope, the individual particles exhibited a slight trembling motion known as the Brownian movement. Although this movement was more marked in the case of the smaller particles, it was insufficient to keep them afloat and they gradually sank out of solution. With the ultramicroscope it had been demonstrated that with increasing fineness of subdivision the motion of the subdivided particles continued to increase in speed and amplitude until it became so vigorous and extensive that the particles no longer settled, but remained permanently afloat; that was, they had a colloidal solution. If the subdivision proceeded still further, they gradually passed into the sphere of true or crystalloidal solutions, wherein the particles of the dissolved substances were reduced to molecular dimensions or even split into ions. The colloidal condition, therefore, was consequent upon an extremely fine state of subdivision

and practically any substance could be converted into or produced in this condition. Some colloids, such as gelatine and gum arabic, were quite sensitive to electrolytes, and readily redissolved after dessication; others, such as pure colloidal metals, were readily coagulated by electrolytes and did not redissolve upon dessication. Zsigmondy had expressed this difference by calling the former reversible and the latter irreversible colloids. The presentation of a diagram taken from Zsigmondy's book served to elucidate this statement. A most interesting property of reversible colloids was that they could protect irreversible colloids from coagulation and permitted them to redissolve after dessication. As little as 1/10,000 of 1 per cent. of gelatine produced this effect in a solution of colloidal gold. Such action was known as "protection" and a reversible colloid exhibiting it was known as a "protective colloid." This power of protection was specific and a reversible colloid might protect one substance and not another. Milk was then considered in the light of the principles of colloid chemistry. Many analyses of milk had included the casein and albumen under the omnibus title of "proteins," thereby obscuring a most important and vital fact—the relation of casein to albumen. The importance of this fact at once became evident when it was stated that casein was an irreversible coagulating colloid, whereas albumen was a reversible or protective colloid. Mother's milk was scarcely coagulated by acid or rennin and by increasing the amount of protection in cows' milk it might be made to act in like manner, which was easily proven by adding a small quantity of gelatine, gum arabic, or other protective colloid. Cows' milk thus treated was not as well or readily curded by acid or rennin. Besides studying the macroscopical effects of protection on the casein, they made certain observations with the ultramicroscope. These observations seemed to show the importance of the subdivided condition of the casein of milk. The influence of "protection," was not, however, confined to the casein, but probably was important in maintaining the emulsion of the fat. The following conclusions were presented: (1) The casein of milk was an irreversible, or coagulating, or unstable colloid, which was protected by lactalbumen, a reversible, or stable colloid. (2) In the modification of cows' milk for infant feeding it was necessary not only to consider the per cent. of "total proteins," fat, etc., present, but to see that the casein was adequately protected. In order that they might not be misunderstood to be only restating the principle expressed in the doctrine of "split proteins," they emphasized the fact that the casein existed in cows' milk in an already formed higher degree of colloidal aggregation. (3) Bald chemical analysis, without taking into consideration the principle of colloidal protectives, was an insufficient criterion for the actual digestibility or availability of food.

The Treatment of Intestinal Indigestion in Children on the Basis of the Examination of the Stools and Caloric Values.—Dr. John Lovett Morse and Dr. Fritz B. Talbot of Boston presented this communication. It seemed to them that, if the stools of children suffering from disturbances of digestion, especially of the intestinal type, were examined in order to determine what constituents of the food were not being utilized and the diet regulated on the basis of these findings, due regard being paid to the caloric needs, much better results could be obtained than by the usual empirical methods. Their experience led them to believe that comparatively simple tests were sufficient to give results accurate enough to form the basis for satisfactory treatment. They had also found that it was a very simple matter to calculate the caloric value of the food and to regulate the proportion of fat, carbohydrates, and proteins. They also found that it was easier to control the diet of the child than that of an adult and that it was at least as easy to get the cooperation of the child in carrying out the diet as it was to get that of an adult. It was probably not far from the truth to state that the average child of four years required about 1,200 calories, or 70 calories per kilo in twenty-four hours; the average child of eight years, 1,400 calories, or 60 calories per kilo in twenty-four hours, and the average child of twelve years 1,600 calories, or 50 calories per kilo in twenty-four hours. There was no objection to giving large amounts of proteins in order to meet the caloric needs when there were disturbances in the digestion of fats or carbohydrates. On general principles, however, it was wiser to keep the proteins down somewhere near the average need, because the metabolism of the proteins required more energy and the products of protein metabolism were more difficult of elimination than were those of the fats and carbohydrates. An excess of proteins, therefore, required an unnecessary expenditure of energy and was consequently not economical. In disturbances of digestion fat might be substituted for carbohydrates and carbohydrates for fat with great advantage, provided the total caloric value of the food was kept up. The fats might be entirely replaced by carbohydrates over considerable periods of time without doing any harm. There was a certain amount of risk in replacing the carbohydrates entirely by fats because of the dangers of developing acid intoxication. A child's stool was normally homogeneous; lumpy and mushy stools were pathological. The reaction was slightly alkaline, weakly, amphoteric, or neutral. A strong acid reaction suggested disturbances in the digestion of fat. A microscopical examination showed a few remains of a vegetable nature, single yellow masses, and a few muscle fibers, a few crystals, rarely starch granules, and microbes. When acetic acid was added a few drops of fatty acid were seen in each field after heating. The stools that deserved special mention were the fatty, the stools of carbohydrate indigestion, and the catarrhal stools. The fatty stools were gray or white in color, dry or of clay-like or creamy consistency, acid in reaction, and of a rancid odor. The carbohydrate stools were brown or golden yellow in color, salve-like in consistency, acid in reaction, acid or sour in odor. The catarrhal stools showed an excess of mucus. This was often associated with protein putrefaction and a foul odor. The character and the quantity of the food taken in the twenty-four hours was known in every instance, so that for all practical purposes the children had had a test diet. The methods of examination employed were essentially those described by Schmidt in his work. The form, coherency, consistency, color, and odor, and the presence or absence of extraneous matters were noted in the macroscopical examination. The microscopical examination was made with a low power objective and later with a No. 7 objective. Three slides were examined; the first contained very thin, crushed-out feces, which was examined in the fresh condition. Another was stained with Lugol's solution and examined under the cover for starch. The third was stained with a saturated alcoholic solution of Sudan III. In the first specimen an excess of undigested muscle fiber, connective tissue, or vegetable fiber could be studied and pathological elements differentiated. A preliminary estimation of the amount of neutral fat, fatty acids, soaps, and starches could also be made. Under the

cover glass the starch granules would stain blue or violet and certain microbes would stain blue. There were practically no unchanged starch granules in the normal stool. An excess was always pathological. Under the third cover glass neutral fat drops and fatty acid crystals stained red. Any increase of fat after the addition of acetic acid indicated the presence of a corresponding amount of the soaps.

Dr. Charles Gilmore Kerley said he had observed that a great many children of different ages, suffering from intestinal indigestion, if given a fair show, would have a particularly good digestive capacity and digest a reasonable diet fairly well. He had not found many children who had a poor starch, protein, or milk capacity, but he had found many whose starch, protein, and milk capacity had been overtaxed. Digestive errors occurring in older children were not due to any peculiarities of the child, but were due, as a rule, to the irrational and peculiar methods of feeding, or the peculiar habits of the child because of his distaste or dislike for this, that, or the other thing. A child should not become imbued with the idea that milk was the only food that was fit. In the runabout age these children required mixed feeding; then there would be less digestive disturbances.

Dr. Thomas S. Southworth said that it seemed to him that an interpretation of stools had been produced which could be taught and placed in text books; hitherto students had to be taught to make their interpretation of stools by actual exhibition of the different forms of abnormality. By means of improved microscopical tests one might be able to anticipate difficulties, since the microscope might show that there was nonassimilation of food even before the symptoms came strongly to the front. Dr. Morse's reports of cases convinced one that after all the successful feeding of the child or infant meant a rationally mixed food of proper proportions. If a microscopic examination of the stools were made, one might more often make such changes in the diet of the infant or child as would be beneficial to the infant. The confirmatory knowledge that one got from such an examination of stools should result in greater success in the future feeding of children.

Dr. John Howland said that Dr. Morse had done a real service in insisting upon an estimation of the caloric values of foods. There seemed to be an impression among some that caloric methods told what kind of food a child should have, while they simply told what amount of food was suitable in order to satisfy the caloric requirements of a certain child. It frequently happened that a child could not digest food in sufficient quantities to satisfy his caloric needs. It was more frequently found that the caloric requirements of the child were exceeded and that a diminution of the quantity of food was followed by prompt relief of symptoms and gain in weight. Data in regard to the metabolism of children after the first year were very few and incomplete; this was due to the fact that twenty-four hour specimens of feces and urine could be collected with more ease in young infants than in older children.

Dr. Godfrey R. Pisek believed that what Dr. Morse and Dr. Talbot had presented would be of particular value to the general practitioner. Such an examination of the stools could be made without a great deal of scientific knowledge, and could be carried out in the home. The microscope would often throw light upon causes of digestive disturbances.

Dr. Herman Schwarz said that in trying to work up some diets for older children in a series of metabolism experiments he had found how meager were the data as to normal figures. In considering the calories and food elements necessary to keep children beyond the age of infancy in nitrogen equilibrium Erich Muller, in a series of thirty-two cases of presumably healthy children, determined their *stoff-* and *kraftwechsel*. He found that with 104 calories per kilo and an intake of 0.55 grams of nitrogen these children gained but so much and were hardly considered normal. Erich Muller found that in children with good appetites or with poor appetites the resorption was the same, but the retention was 0.03 grams per kilo as against 0.05 grams, a difference of 40 per cent. Dr. Schwarz believed that the reason this work had not been taken up more enthusiastically was because the internists had not decided upon the value of Schmidt's work. The great difficulty had been with fat indigestion. It was not easy to judge of fat indigestion by a microscopical examination of the stools. Even a chemical analysis of the stools alone did not furnish absolute data, for some of the fat contained in the stools might have come from the intestinal walls. In spite of this the method was one easily followed out and apt to give valuable clinical data. There was, however, a series of cases in which there was an indigestion without any change in the stools. A point in the treatment of these cases was rest; often placing the child on his back for an hour and a half every afternoon improved the digestion. His experience had taught him that milk was usually well borne, if not as whole milk, then in some form of skimmed or diluted milk.

Dr. Elias H. Bartley said that the accurate estimation of the quantity of fat in the stools was a very valuable addition to their knowledge; if this could be done, it would give much information which he had been very desirous of having. All admitted that fat indigestion was certainly a very common thing in intestinal disturbances occurring in early childhood as well as in infancy. In some of his cases where there was evident fat indigestion he had been obliged to reduce the fat in the milk down to between 1 and 2 per cent. in order to give the children any sort of comfort; in such cases he had found that some cases would tolerate butter if given with cereals, or with bread or zweibach; but, on the other hand, they would not tolerate the same amount of fat if given in the milk. The only interpretation of this he could give was that it was the cereal that broke up the butter and made something like an emulsion in the stomach. Dr. Bartley said that he had at the present time under his care a child where he was obliged to keep the fat in the milk down to about 2 per cent. If more than that was given it was evidenced by the putty character of the stools, an excess of mucus, excoriation of the nates, etc. All believed that when they gave a fairly well balanced food the question of quantity was very important. And here was where the heat value of the food came in. He had adopted in his feeding, as a minimum for children under one year of age, one gram of protein for every pound of body weight per day. That meant giving of about one ounce of milk for every pound of body weight per day. But some children would not obey the rule as to caloric values when it came to fats. All these calculations for determining the caloric value of the foods of infants must be modified to suit the baby under trial. These calculations were of value merely to check their feedings; it told them what the baby ought to have in its food to properly nourish it.

Dr. Fritz B. Talbot of Boston said that in cases of starvation some fat was excreted and was found in the stools. Under normal conditions the amount of

fat excreted in the stools did not increase when food containing fat was given. On this basis, he believed that the amount of fat seen under the microscope gave an estimate of the amount of fat in the stool. Normally about 20 per cent. of the dry stool was composed of fat. There was no difficulty in recognizing an absolutely normal or markedly pathological stool. He had made a rule based on experience with the stools of older children that when, with a No. 7 objective, he found six, seven, or eight droplets in each field, and when, after the addition of glacial acetic acid and heat, nearly the whole preparation showed fat, he called that an excess. But there was to be taken into account the individual equation in this, as in other microscopical examinations. With regard to Dr. Bartley's two cases which he reported, Herter and Kendall had shown in their bacteriological work on stools that an excess of one component would change the bacteriological flora; therefore it was fair to assume that the predominance of certain types of bacterial flora might cause indigestion. It was well known that overfeeding of protein would cause fat indigestion, and he believed that overfeeding of fat could cause sugar indigestion. In Dr. Bartley's second case the increase in the fat in the milk formula might have caused sugar indigestion, and the products of sugar decomposition caused the burning and irritated buttocks. Experience had shown that the microscopical examination of the stools was a very valuable aid in diagnosis and treatment, and he had found that it was valuable in its negative as well as in its positive results. When he saw a youngster with some obscure dyspeptic upset and examined the stools and found nothing abnormal, he felt that it was safe to say that simple method of treatment would cure the indigestion.

Dr. William P. Northrup said that many years ago when exact percentage methods of infant feeding were being investigated one heard frequent remarks about the infant's stomach not being a test tube and that percentage feeding might and might not meet the needs of the infant. However, the practitioner had profited by this method. A cook might prepare an excellent dinner by adding a pinch of this ingredient, a dash of that, and a cup of another, and yet be unable to tell the next day what she had put in it. But after all, fixed and exact data were valuable for the many dinners, the many cooks, and the improvement of method. What had been presented to them was another exact method of feeding infants and children as determined by their needs. Dr. Northrup considered this contribution valuable. If one saw an excess of any one ingredient, it certainly furnished a control; it furnished a point of departure which was destined to be useful in the future.

Dr. L. E. LaFetra said that some points emphasized might be still further dwelt upon, especially that a microscopical study of the stools would aid one in avoiding certain errors which without it were not easy to discover. He agreed with Dr. Morse that the stools in carbohydrate indigestion frequently looked like normal stools, being often brown and smooth. It was quite common to find infants losing in weight when the caloric value of the food was too high. The caloric method was not a method of feeding, but merely told whether a child was getting too much or too little food. It therefore served as a measure for any method of feeding.

Dr. John Lovett Morse of Boston said there were a few points on the clinical side of the subject to which he would refer. He agreed with Dr. Kerley that the prolonged use of milk was often the starting point of indigestion in infants, but he did not agree with the statement that milk was not well borne by older children with indigestion. In proper amounts milk usually did agree with them, although at times it might be necessary to give skimmed milk. The majority of cases of indigestion in children could be straightened out by common sense methods of feeding and such careful treatment was not generally required. As a rule he knew what the condition was from the macroscopical examination of the stools, but occasionally he was very much surprised by the results of microscopical examination and was prevented from falling into serious error. He quite agreed with Dr. Schwarz in what he had said regarding the importance of rest. Rest was an important adjunct not only in intestinal indigestion, but in children who were run down from any cause.

Election of Officers.—*Chairman,* Dr. Eli Long; *Secretary,* Dr. William Shannon.

WILLIAMSBURG MEDICAL SOCIETY.

Stated Meeting, Held October 11, 1909.

Dr. William Linder in the Chair.

Symposium on Acute Anterior Poliomyelitis, Pathology.—Dr. Israel Strauss of Manhattan read this paper. He said that until the epidemic of this disease that had prevailed in Sweden in 1905, the pathology had not been carefully studied. Wickman wrote a monograph as the result of the careful study of 1000 cases. Harbitz and Scheel made an exhaustive investigation of the pathological anatomy of the disease, on the basis of a number of outbreaks occurring in Norway. It was only in 1907 that the speaker was able to obtain for the first time in this country pathological material. By means of a fine series of microphotographs thrown upon the screen he reviewed the pathological anatomy of this disease. He showed, in agreement with the former observers, that the disease of the cord was more extensive than had been formerly realized, and that the brain was likewise involved. In the sections that he presented, the brain showed but little edema and congestion; the same was true of the cord, but what it did show was characteristic. The grey matter of the cord was of a light pinkish blue, while the white matter had a curious translucent appearance. The inflammatory process in the cord involved the pia mater, the white matter, and the gray matter. It appeared as if the inflammation spread inward from the pia mater along the blood-vessels. There was a marked perivascular infiltration and infiltration of the adventitial wall. The exact origin of the infiltrating cells was in doubt. The most striking phenomena was the marked edema of the white and gray matter. In the latter there were foci of mononuclear and polymorphonuclear cells. These were apparently not identical with the polymorphonuclear leucocytes, for they had no neutrophite granules, but were probably cells of the wandering type. The ganglia in the gray matter of the cord showed various stages of degeneration. The disease was not a localized process in the cord, but was a general involvement of both cord and brain. This was shown clinically in the early stages by the pain, hyperesthesia, arthralgia, rigidity of the neck, and other manifestations, simulating a true meningitis, but in reality due to an infiltration of the pia, of the white, and grey matter, and to the pressure upon the sensory and motor ganglia. The areas of infiltration were quite distinct in the pons and in the basal ganglia. The extensive paralysis that occurred in the early stage of poliomyelitis was the result of the widespread edema and transudation in the cord. The residual paralysis was the result of the degeneration of the cells in the anterior horns, and in the grey matter chiefly at the base of the brain, from pressure necrosis.

One year ago the speaker had inoculated various laboratory animals, such as mice, guinea-pigs, and rabbits, with an emulsion made from the spinal cord of a fatal case of poliomyelitis. A guinea-pig thus inoculated developed paralysis of the hind legs and died. There were found on autopsy extensive hemorrhages of the cervical region of the cord. Langstein and Popper of Vienna had been the first to inoculate monkeys and other animals by means of interperitoneal injections of emulsions of spinal cord from a fatal case of poliomyelitis. Only two monkeys had shown any effect of the inoculation; one had become severely ill in the sixth day, and had died two days later, and the other had become paralyzed in the posterior limbs on the seventeenth day and had been killed two days later. In both animals the spinal cord had shown the lesions typical of poliomyelitis, but none of the other organs had shown any changes. Efforts to inoculate other monkeys with material from these animals had failed. The speaker had plated the cerebrospinal fluid obtained from various cases of poliomyelitis upon different culture media, without obtaining any cultures. A monkey was inoculated intraperitoneally with the blood from a case of poliomyelitis; this monkey survived with no untoward effects. An emulsion of cord from a case of poliomyelitis inoculated upon a sugar medium produced three colonies of a gram negative organism that had not yet been described. One of the monkeys inoculated developed an acute endocarditis, but none of the lesions of poliomyelitis. It appeared as if the latter disease invaded the system through blood and lymph channels. It did not leave any part of the cord uninvolved. It was possible that the pia mater was involved secondarily. The speaker believed that the cerebrospinal fluid did not contain the virus nor did the blood. The only thing that held the virus was the central nervous system. The virus was probably not a bacillus, else it would have been stained by one of the numerous stains employed. The histological lesions of poliomyelitis were strikingly like those of rabies. In both the ganglion cells were affected. In both there were similar lesions in the ganglia on the posterior nerve roots. Both were transmitted by means of material from the cord. From the curative viewpoint it was evident that one was confronted by a difficult proposition, for the pathological anatomy showed that the spread of the infection might be stayed, but not the original onslaught, whose damaging effects could not be foreseen or prevented. If a specific vaccine could be discovered, nothing short of universal vaccination would suffice to combat the disease.

The Symptomatology and Diagnosis of Acute Poliomyelitis.—Dr. W. P. Northrup of Manhattan read this paper. He said that the form of the disease seen in the present epidemic had features different from those seen in previous epidemics. He cited a few cases to illustrate the symptomatology. Little J. F. after witnessing the Hudson-Fulton parade was taken home, feeling tired and ill. One and a half days later he vomited, had fever, and aches in his muscles. He was sick for two days with symptoms suggestive of ptomaine poisoning. Following this he had retention of urine, and paralysis of both legs. Another case was admitted at the Presbyterian Hospital presenting similarly retention of urine; 15 oz. of the latter had been drawn off by catheter. In this case there was also paralysis of both legs. Another case cited was that of paralysis of the soft palate, as one of the symptoms of a polioencephalitis. The pathological process in poliomyelitis was a diffuse one; the disease was really a form of myelitis, affecting sensation, motion, the bladder, the rectum, the limbs, etc. A photograph was presented showing a "bulging-belly" child, in which there was an apparent abdominal hernia due to paralysis of the abdominal muscles. The diagnosis of the disease was next discussed. In the presence of an epidemic one was to suspect any case that began like a sharp attack of indigestion or of meningitis. With such an onset one was to have in mind pneumonia, acute cerebrospinal meningitis, tuberculous meningitis, and acute indigestion. The occurrence of paralysis settled the diagnosis. As regards the treatment of the disease, one had to consider that it was like a lightning stroke, and that there was no way of stopping it. Lumbar punctures repeated were worth while provided that at the first puncture the cerebrospinal fluid was found under pressure.

The After-Treatment of Acute Poliomyelitis.—Dr. Reginald Hall Sayre of Manhattan said that the after-treatment included internal medication, electricity, manipulation, and mechanical treatment. Internal medication included chiefly the use of strychnine. Hypodermatic injection had no advantage over the use of strychnine by mouth. The good results in the former case had been due rather to the large doses employed. It was desirable to administer the strychnine in increasing doses up to the full physiological effect. Electricity was of great use. It was quite comforting to the patient; the limbs became less blue and cold. In many cases considerable improvement followed its use. Interrupted galvanism and finally interrupted faradism were to be used. The smallest dose capable of causing the reaction was to be given, but not enough to cause pain. Manipulation was essential in the after treatment. Massage was to be given. It was no longer true that the presence of the reaction of degeneration made after treatment futile. Cases had been seen in which the reaction of degeneration was present, and in which recovery had occurred. Cases that seemed absolutely hopeless still had a chance to get better. Improvement was to be expected in many cases as long as two years after the initial attack. Unless stimulation was kept up for a long time, one was apt to be disappointed. It was extremely important that the body weight should be borne in a normal manner. It was desirable to put on the paralyzed limb a brace with a limited-motion joint; the lighter the apparatus the better. Surgery was often necessary. For talipes, if necessary, a tenotomy was to be done. The open operation was not required. Non-union of the cut ends of the tendon frequently resulted from too tight a bandage. Transplantation of tendons was frequently a valuable procedure.

Pathological Society of Philadelphia.

At a stated meeting held December 9 Dr. James E. Talley presented a specimen of "Ulcer of the Cardia." The patient was a man 34 years old with marked arteriosclerosis who was seized with symptoms of shock in conjunction with hematemesis, enterorrhagia, and severe abdominal pain, and terminating fatally. On post-mortem examination an ulcer was found at the cardiac extremity of the stomach, and in the depths of which was a ruptured sclerottic artery. Dr. H. S. Wieder presented "Two Ovarian Dermoid Cysts." One was of ordinary size and of the usual type, with sebaceous contents, together with hair and a bony formation resembling a scapula. The other occurred in connection with an ovarian cyst, and was of immense proportion. Drs. T. H. Weisenberg and Joseph McFarland presented a "Cerebellopontine Tumor." The patient was a man who had been treated by repeated operation and otherwise for several years for tic douloureux. Drs. David Riesman and A. G. Ellis presented a communication upon "Cases of Toxemic Jaundice." They reported several cases in men employed in an establishment for the manufacture of articles made from bone who presented jaundice with fever and other symptoms, but without the physical signs, of acute yellow atrophy of the liver. Dr. A. G. Ellis read a paper entitled "The Occurrence of Eosinophile Cells in the Respiratory Tract." Dr. Samuel Stern read a paper entitled "The Value of the Noguchi Butyric Acid Reaction

in Syphilitic and Parasyphilitic Affections." His observations led to the conclusion that a negative response is of more value than a positive one. Dr. Leo Loeb read a paper entitled "The Cell-granule in Their Relation to Functional Conditions in the Protoplasm." Drs. Herbert Fox and C. Y. White presented a communication entitled "Tumors in the Lower Animals" in which they recorded the cases in which new-growths were observed in animals dying at the Philadelphia Zoological Gardens.

Varicella	84	—
Typhoid Fever	21	9
Whooping Cough	17	5
Cerebrospinal Meningitis	3	6
Malarial Fever	—	—
Totals	1,680	256

Intrapleural Injection of Sterlized Air in Pleurisy with Large Amount of Effusion.—A. Borgherini states that it is necessary in cases of large effusions into the pleural cavity to be very cautious in attempting to remove the fluid, and to remove only a portion at a time, lest we have serious consequences. When we combine with thoracentesis the injection into the pleural cavity of sterilized air the operation is no longer dangerous, and may be carried out at one sitting, all the fluid being removed at once. The air is sterilized and desiccated by passing it through a solution of permanganate of potash and caustic soda. In no case has it been necessary to repeat the operative procedure for reappearance of the fluid. The action of the air is mechanical. It lessens the weight of the thoracic contents, and aids the act of respiration. It prevents a too rapid expansion of the compressed lung, lessening congestion and edema of the lung, which may cause severe hemorrhage. In cases in which the lung does not expand it lessens the pressure of the other organs on the diseased side of the thorax and preserves the position of the mediastinal organs.—*La Riforma Medica.*

Health Reports.—The following cases of and deaths from smallpox, yellow fever, cholera, and plague have been reported to the Surgeon-General, Public Health and Marine-Hospital Service, during the week ended December 31, 1909:

OBSERVATIONS ON PELLAGRA AT THE PEORIA STATE HOSPITAL, PEORIA, ILL.*

BY J. F. SILER

AND

H. J. NICHOLS,

CAPTAINS, MEDICAL CORPS, U. S. ARMY.

SUMMARY OF HEADINGS.—I. The Peoria State Hospital: (*a*) Description, (*b*) Character of Patients.
II. Pellagra at the Peoria State Hospital: (*a*) Recognition and Extent of the Disease, (*b*) Occurrence in Previous Years, (*c*) General Data.
III. Clinical Picture of Pellagra: (*a*) Cutaneous Symptoms, (*b*) Digestive Tract Symptoms, (*c*) Nervous and Mental Symptoms.
IV. Treatment and Mortality.
V. Pathology of Pellagra: (*a*) Laboratory Examinations, (*b*) Autopsies.
VI. Epidemiology: (*a*) The Question of Infection, (*b*) The Question of Intoxication.
VII. Summary.

I. The Peoria State Hospital.—A thorough comprehension of the pellagra problem at the Peoria State Hospital necessitates a brief statement concerning the general character of the institution and its patients. The institution is located about five miles from Peoria on a plateau overlooking the valley of the Illinois River. It is constructed on the cottage plan, the first floor of each cottage being used as a general sitting room, with bedrooms on the second floor, and dining rooms in basement. There are two hospitals, male and female, to which patients are transferred when sick or disturbed. The cottages vary in size, accommodating from 50 to 150 patients. The institution grounds are not inclosed by wall or fence, their limits being imaginary lines. In none of the cottages are the windows barred. All inmates, with the exception of those cases known to be escapes, are allowed the freedom of the cottages and grounds, and the consequent exposure to sunlight during the summer is practically unlimited. This fact may, in part, explain the striking development of the pellagrous erythema.

For the care of its insane, the State of Illinois is geographically divided into districts, each district having its insane asylum. The rapid increase in the population with consequent proportionate increase in insanity, so overtaxed these institutions as to necessitate the transfer of the hopeless, incurable cases to the various almshouses throughout the State. To relieve the overcrowding and correct these deplorable conditions, the institution at Peoria was established in 1902, its official designation being, The Asylum for the Incurable Insane. The first 500 inmates of the Peoria State Hospital were drawn from other institutions throughout the State and were made up of the hopeless, untidy, incurable class.

In 1904 the capacity of the institution was greatly increased and the almshouses throughout the State were relieved of their old hopeless, incurable cases of insanity, by the transfer of such patients to the Peoria institution. Only within the past two years have acute cases been committed directly to the institution, and the majority of the patients belong to the chronic, incurable class. The following statistics show the growth of the institution: June 30, 1902, 622; 1903, 698; 1904, 762; 1905, 1,449; 1906, 1,729; 1907, 2,008; 1908, 2,021; 1909, 2,150. The patients are drawn from 102 counties throughout the State.

In 1908 the average age was 47 and the average age of those who died was 57. The death rate in 1903 was 3 1-5 per cent.; 1904, 6 1-3 per cent.; 1906, 10 per cent; 1908, 15 per cent. This marked increase in death rate is accounted for, in part, by old age; it is altogether probable, however, that the appearance of pellagra among the inmates has had some bearing on the increase in cases diagnosed as general paralysis of the insane; this increase being shown as follows: 1903, 0; 1904, 3; 1905, 30; 1906, 55: 1907, 47; 1908, 65. It is quite probable that

*As the result of a request from Dr. George A. Zeller, Superintendent Peoria State Hospital, and Dr. James A. Egan, Secretary of the State Board of Health of Illinois, to the Surgeon-General, U. S. Army, the writers received orders from the War Department, in the latter part of August, 1909, to proceed to Peoria, Illinois, for the purpose of studying pellagra, which had made its appearance among the inmates of the Peoria State Hospital. Soon after our arrival the State Health authorities also secured the services of Dr. W. H. Buhlig of Chicago, and a study of the disease, continuing for more than a month, was made in conjunction with the State Health authorities and the members of the medical staff of the institution.

The work was apportioned among the working party as follows: under the supervision of Dr. Buhlig, Mr. Holmes of Dr. Buhlig's Laboratory took up the examination of urine, differential white cell counts, gram stains of feces and certain cultural work; Dr. George Michell of the medical staff studied and tabulated the skin lesions and digestive tract symptoms; Dr. E. Z. Levitin of the medical staff took up the mental and physical condition of the male patients; Dr. C. R. Bell, the mental and physical condition of the female patients; to Dr. R. F. Winsor was assigned the blood counts, hemoglobin estimation, and assistance in autopsy work; Dr. Welton of Peoria made a study of the eye changes; D. H. Baldwin, D.D.S., of Peoria made a dental examination. The writers took general charge of a clinical study and a study of epidemiology.

The writers desire to take this occasion to express to Dr. Zeller, Superintendent, their thanks for his most hearty cooperation, his uniform courtesy, and for innumerable personal favors. We are also indebted to Dr. James A. Egan, Secretary State Board of Health of Illinois, for his active cooperation. We are under many obligations to the members of the medical staff of the institution, and desire to perticularly express our thanks to Dr. Michell, Dr. Watkins, Dr. Levitin, Dr. Bell, and Dr. Winsor for their enthusiastic and active assistance.

This report will also be published in the Bulletin of the Illinois State Board of Health.

many of these cases were pellagrous in character. The patients making up the population of the institution may well be designated as dregs and wrecks of humanity, and it is not to be wondered at that if pellagra is to be found in Illinois it should make its appearance among the inmates of this institution. Only a small number of cases have been reported from other State institutions.

II. Pellagra at the Peoria State Hospital.—Early in August Dr. F. J. Griffin, of the medical staff of the institution, reported to the superintendent, Dr. Zeller, a case showing symptoms of the disease, and after examination by Dr. Zeller and the medical staff a diagnosis of pellagra was made. A superficial examination of the inmates of the institution by Dr. Zeller revealed the fact that many patients presented the clinical picture of pellagra. The diagnosis of pellagra was confirmed a few days later by Dr. C. H. Lavinder of the Public Health and Marine Hospital Service. After becoming convinced of the actual presence of the disease, Dr. Zeller brought the subject to public attention and has been very active in arousing interest in the subject. He has been elected Secretary of the National Association for the Study of Pellagra, the next meeting of which will be held at his institution.

On August 23 a thorough examination of the inmates was undertaken by the writers, with the result that 66 inmates were found who presented the clinical picture of an acute attack of pellagra, while 150 additional patients were classified as atypical or suspicious. Cases presenting typical symptoms rapidly increased in number, and it could conservatively be stated that during our stay in Peoria we had seen more than 125 cases of undoubted pellagra. As the disease was not recognized as such until August 10, in the midst of the period of acute exacerbation, no accurate statistics are available as to the extent of the disease prior to this date. The medical officers in charge of the hospitals of the institution, after a study of the clinical records and death reports, stated that, in their opinion, between May 1 and August 10, 26 deaths occurred in the hospitals from this disease. Cases have continued to appear since our departure. It may conservatively be stated that at least 175 of the patients showed evidence of pellagra during the past summer. A series of one hundred cases were selected for detailed study, and the statistical tables included in this report are based on this number.

There is overwhelming evidence establishing the fact that pellagra has been prevalent in the institution for at least three or four years. Among the file copies of letters written by the superintendent to relatives and friends of inmates who died, several referred particularly to the appearance of sunburns on the backs of the patients' hands, attributing these burns to excessive exposure to fresh air and sunlight. Coroners' inquests have been held on patients who were thought to have incurred severe scalds of the feet by reason of carelessness on the part of attendants. Attendants have been dismissed for allowing inmates under their charge to become badly scalded on the feet and legs, presumably during baths. Early in the spring of this year the superintendent, in a lecture to the nurses, stated that sunburns on the backs of the hands had been altogether too common during the past summer and their recurrence during the summer of 1909 would not be tolerated. It is now realized that a large proportion of these cases were not ones of severe sunburns and scalds, but were cases of pellagra. The members of the medical staff, and nurses who had been connected with the institution for several years were questioned concerning the appearance of the symptoms of pellagra during previous years. The fact was easily established that 72 per cent. of pel-

lagrous patients had suffered from previous attacks, these acute attacks being recalled by two, three, four and occasionally five and six different medical officers and nurses.

As will be seen in Table No. 1, the average number of previous attacks was two. Of those suffering from previous attacks, 25 per cent. gave history of three previous attacks, 52 per cent. gave history of two previous attacks, and 23 per cent. gave history of one previous attack.

Sex.—Of the cases included in this study, 44 were males; 56 females. The male and female inmates of the institution were about equal in number, and it is believed that pellagra affects both sexes in about the same proportion. This finding is at variance with the experience in the asylums in the Southern States.

Occupation.—A large proportion of these cases had been insane for many years, and in many instances, incomplete records had been forwarded to the institution with them. Of cases showing records of previous occupation, 29 were housewives, 13 were farmers, 15 were laborers, 1 was a photographer, and 1 was a clerk.

Age of Pellagrous Patients.—As will be seen in Table No. 1, the youngest patient was 22; the oldest 85; the average age being 50 years. 57 per cent. of the cases were between 40 and 59 years of age. The distribution as to age decades was as follows: From 20 to 29, 4 cases; 30 to 39, 18; 40 to 49, 28; 50 to 59, 29; 60 to 69, 16; 70 to 79, 3; 80 to 89, 2.

Social Conditions.—Circular letters were forwarded to friends and relatives of these patients for the purpose of collecting, if possible, data relative to social status; institutional life; the use of corn products as an article of diet, and any possible facts which might indicate the appearance of the disease before commitment to institutions. Forty replies were received and the statements of possible interest were: (1) A large proportion of the patients had been asylum and almshouse inmates for many years; (2) In only a small percentage of cases had corn products been used as an article of diet, prior to commitment to institution, and in no case had corn products continuously been used; (3) With two or three exceptions these patients had been extremely poor and their sanitary surroundings in their home life had been bad; (4) In cases Nos. 28 and 59 it had been noted that the backs of the hands showed "salt rheum" and "sunburns" during the summer months.

Accompanying Organic Disease.—Inasmuch as Neusser attributes great importance to a sickly condition of the patient as a predisposing factor in pellagra, an investigation of concurrent diseases was made. 36 per cent. of the cases showed organic disease other than pellagra, exclusive of amebic dysentery. Amebic dysentery, though present in a large percentage of the cases (Table No. 2), had not been definitely recognized as such. Among organic diseases noted were: 12 cases epilepsy; 8, pulmonary tuberculosis; 12, organic heart disease. These diseases occurred in pellagrous patients in about the same proportion as was noted in the general population of the institution.

III. Clinical Picture of Pellagra.—In studying the literature on pellagra, one is struck by the fact that the symptomatology of the disease is an amazingly variable and changeable one. Many of the symptoms termed as characteristic of pellagra are by no means characteristic of this disease alone, but are of common occurrence in other diseased conditions. The symptom-complex is said to vary in different sections and at different seasons, and this variation, as noted in the literature of the disease is, in some instances, so striking and contradictory as to lead one to question the statement that pellagra is a disease entity.

In studying the cases at Peoria, an effort was made to determine as to whether or not any constant symptoms were present, which might be relied on in all cases for diagnostic and prognostic purposes. In considering the cases at Peoria, it must be remembered that the cases were limited to the insane, and, with few exceptons, it was manifestly impossible to place any reliance on subjective symptoms. Under these circumstances, in attempting to arrive at any definite conclusions, objective symptoms only were worthy of study.

European observers, in their clinical descriptions of pellagra, state that there are three cardinal groups of symptoms:

(1) Erythema; (2) digestive tract symptoms; (3) nervous and mental symptoms. In these cases, a study of the erythema, digestive tract symptoms, and, to some extent, the nervous symptoms, was possible.

The clinical picture of the disease showed such wide variation as to warrant a division of the cases into at least two types. These types may be designated as (1) mild attacks (probably of recent origin); (2) severe attacks (probably chronic in character and of several years' duration).

Mild Attacks.—The patients suffering from mild attacks included those in which an erythema was noted, involvement of the mouth was slight or absent, and diarrhea, if present, was of no consequence and of short duration. In these patients constitutional symptoms were absent and the patients were apparently perfectly well, except for the cutaneous lesions.

Severe Attacks.—In patients suffering from severe attacks the clinical picture was altogether different. The erythema frequently ended in bleb formation, the inflammatory reaction involving the tongue and buccal mucosa was intense, the diarrhea was severe and persistent, and dysenteric stools were frequently noted. Constitutional sysmptoms were the most striking feature of these cases. The picture was one of a prefound toxemia and physical failure was rapid and progressive. In some cases the toxemia was so severe as to change a picture of health to one of death within the course of a week.

The acute typhoidal type of the disease, referred to by some authorities, was not observed among these cases. While some cases presented the symptoms attributed to the acute typhoidal attacks, an investigation into their previous history showed that they had suffered from acute exacerbations during previous years and this warranted their inclusion among those cases suffering from severe or chronic attacks.

Cutaneous Symptoms.—No cases were included except those showing skin symptoms. Our conception of the disease in this country, at the present time, is a somewhat hazy one, and it is believed that the diagnosis of pellagra is unwarranted in the absence of skin symptoms. Among the cases at Peoria the skin lesions first appeared on the dorsum of both hands as bright red erythematous areas, irregular in outline, and varying as to size. The color of the skin over affected areas would grad-

ually assume a darker shade and after a few days a characteristic purplish, dusky red color would be in evidence. Occasionally the skin lesions would show a dark, greenish-bronze cast. The line of demarcation between affected and healthy skin was usually distinct and sharply outlined. After about ten days the color would begin to fade and desquamation of the epidermis would occur. Desquamation began over the area first affected and the squamæ were usually thin, fine, and bran-like. Desquamation was, as a rule, complete within a month after first appearance of the lesion. After complete desquamation the skin was smooth, soft, and pinkish in color, a distinct line of partially desquamated epithelium being noticeable around the edges, showing plainly the extent of the lesion.

In 36 per cent. of the cases the erythema appeared also on the forearms, usually involving the dorsal surface only. An erythema was occasionally noted on the front of the forearm, usually the radial aspect, and in some instances the erythema completely encircled the wrist in the form of a cuff. The extent of area involved seemed to have no bearing on prognosis. The effect of direct sunlight in bringing out the erythema was beautifully demonstrated in Case No. 100. This patient was admitted to hospital during the desquamative stage, and it was noted that during the summer it had been his custom to wear around both wrists bands of cotton cloth about one-half-inch wide, snugly fitting and incapable of removal except by cutting. When these wristlets were removed it was noted that the area of the skin covered by them was normal, while immediately above and immediately below these bands of healthy skin, active desquamation was taking place. In 17 per cent. of the cases, erythematous areas appeared on other portions of the body, their usual location being the face and neck. Occasionally blotches, resembling hemorrhages underneath the skin, reddish brown in color, appeared on the upper and lower lids encircling the eyes. Desquamation of these areas appeared to be very slight. In two cases erythematous areas were noted on the legs, but in no case was it observed on the dorsum of the feet.

The skin lesions were not noted on the palmar surface of the hands, except by occasional slight extension from the dorsum over the thenar eminence. In a few of the more severe cases, the vulva showed marked excoriation and irritation, but as the lesions could be attributed to other causes, they were not classed as distinctly pellagrous. Vaginitis was noted in a few cases only.

Symmetry.—The most striking feature of the skin lesions was the symmetry, which was noted on the neck and face as well as the hands and forearms. Perfect symmetry in the lesions on both sides of the body, as to location and extent, was noted in 97 cases of the 100.

Bleb Formation.—In 10 per cent. of the cases at Peoria, bleb formation was associated with the erythema. In some cases vesicles only were noted, while in others the vesicles became confluent, forming one large bleb. Bleb formation occurred only in cases showing severe constitutional effects, and bore an important relation to prognosis. Death occurred in 66 per cent. of the cases showing blebs. Edema of the hands was noted in several cases, more particularly those showing blebs. Pain on pressure was noted in one or two cases only, but the general insensibility to pain among the insane renders this observation of no value as a negative finding. In some cases a recrudescence of the erythema occurred.

It occasionally happened that the erythema appeared on one hand before the other became ex-

tensively involved, but in the course of time the lesions on both hands would show perfect symmetry.

Seborrhea.—Marked seborrhea involving the alæ of the nose was noted occasionally, but was by no means of common occurrence.

Digestive Tract Symptoms.—Mouth. In general terms it may be said that there were no distinct and characteristic mouth symptoms common to all cases. In 71 per cent. of the cases a variable degree of redness of the tongue or buccal mucosa was noted. In the milder cases this redness could be attributed to digestive disturbances, diarrhea, dysenteries, lack of personal care of the teeth and general bad condition of the mouth. The following extract from the 1908 report of Dr. W. J. Weatherwax, dentist for the institution, will convey some idea as to the general condition of the inmates from the standpoint of a dentist: "Many mouths are a mass of decayed teeth and roots, the remaining teeth, if any, entirely covered with deposits of tartar, the roots surrounded with badly inflamed gums with pus exuding constantly from pockets."

D. H. Baldwin, D.D.S., the dentist for the institution, examined the cases of pellagra on two different occasions, and his general conclusions are as follows: "1. In the mouths of patients suffering from pellagra we find in the early stages of the disease marginal gingivitis. As the disease progresses the inflammation gradually extends until the whole mucous membrane of the mouth is involved, and in the more severe cases, the gum and mucous membrane are soft and spongy and covered with mucous patches so soft that you will often find impressions of the approximal surfaces of the teeth. 2. I find a much improved condition in the mouth of the pellagra patients since my last examination one month ago. As the outward symptoms disappear the mucous membrane of the mouth assumes a normal condition."

In those cases presenting severe constitutional symptoms, the tongue was edematous and fiery red. The buccal mucosa was intensely inflamed. Ulcerating patches were frequently noted throughout the mouth, tongue, and buccal mucosa and excessive secretion of saliva was of common occurrence. In some cases the inflammatory reaction was so intense as to cause great pain, prevent protrusion of the tongue and greatly interfere with the taking of food. The intensity of the mouth symptoms had a direct bearing on immediate prognosis. In those cases presenting severe oral symptoms, death almost invariably occurred, even though the severe inflammatory reaction cleared up to a large extent.

Diarrhea and Dysentery.—Diarrhea or dysentery was present in 85 per cent. of the cases, but, as will be noted in Table No. 5, these intestinal disorders may, to a very large extent, be attributed to factors other than pellagra, *per se*. The percentage of cases showing protozoal infection—amebæ and flagellates—was very high (see Table No. 5). The milder cases suffered from diarrhea of short duration. Eighteen per cent. of the cases presented the clinical picture of amebic dysentery—frequent small stools, containing blood and mucus and of very offensive odor. We are of the opinion that, so far as the Peoria cases were concerned, it could not be said that diarrhea or dysentery was an essential symptom of pellagra. Sixty-six per cent. of those cases showing the clinical symptoms of dysentery either died or were rapidly failing and this complicating factor should be considered in determining death rates from pellagra. It was very evident, however, in the cases showing severe constitutional effects, that some additional factor other than flagellate and amebic infection was present. In the severe cases the physical failure was rapid and the patients presented the picture of a profound intoxication. The gross appearance of the stools varied from the normal to the dysenteric, dependent largely upon the presence or absence of protozoal infection.

The time of appearance of diarrhea in relation to other symptoms varied. In some instances its appearance was coincident with the appearance of the skin symptoms; again, it had existed in chronic form prior to the appearance of the skin symptoms, as would naturally be expected in amebic and flagellate infection; and in several of the severe cases proceeding to a fatal termination the diarrhea became persistent after the skin lesions had disappeared. In some of the fatal cases, prior to death, the skin lesions had disappeared and dysentery had been checked, the fatal issue being apparently due to exhaustion resulting from a severe toxemia.

Vomiting was seldom noted, and vertigo was an infrequent symptom.

The temperature was normal with but few exceptions. In two or three cases the temperature rose to 105° and 106° F., just prior to death.

Nervous Symptoms.—The condition of the important nerve reflexes is charted in Table No. 3. The only reflexes showing change of diagnostic value were the patellar and plantar. The patellar reflex was abnormal in 80 per cent. of the cases. A little less than two-thirds (62 per cent.) of the 100 cases showed increased patellar reflexes, while in 18 per cent. the reflex was diminished. In 68 per cent. of the cases the plantar reflex was abnormal, 53 per cent. showing increased reflex and 15 per cent. showing diminished reflex. Both the patellar and plantar reflexes, when abnormal, were in the large majority of cases, increased. Occasionally an increased reflex on one side would be accompanied by a normal or diminished one on the opposite side.

As some continental authorities attach some prognostic value to the Babinski reflex in pellagra, the cases were examined for this reflex. The Babinski was obtained in fifteen of the cases, and of this number only three died.

Spinal Tenderness.—This was noted in only 14 per cent. of the cases. In ruling this out as a symptom ordinarily present in the disease, it must be remembered that these cases developed among insane people in whom the sense of pain had been lost to a very great extent.

Mental Symptoms.—As all of these cases were insane and many of them had been so for many years, it was impossible to determine the exact extent of mental disturbance which might be attributed to pellagra. An examination of Table 1 shows that many of these cases had been asylum inmates for a great number of years, the average duration of insanity for the series being 13 years. Examination of Table 1 shows also that many of these patients had been inmates of the Peoria institution for several years, the average number of years being four, and this fact would seem to be a strong indication that the exciting cause of the disease is present in the institution. At the

same time, none of the nurses, attendants or other employees have, as yet, shown any evidence of pellagra.

Ten per cent. of these cases were committed to the Peoria State Hospital from civil life during the past two years, and it is very probable that some of this number are cases of pellagrous insanity. Of the ten cases referred to, the duration of insanity was as follows: Four cases adjudged insane 2 years ago; 5, 1 year ago; 1, 6 months ago.

The psychosis in these cases was as follows: Four dementia præcox, 1 alcoholic insanity, 1 involution psychosis, 2 paresis, 2 dementia unclassified.

The mental symptoms noted by continental authorities as being indicative of pellagrous insanity are, to say the least, not clear cut and definite, and it is extremely doubtful if expert psychiatrists in this country would state definitely that the Peoria cases were ones of pellagrous insanity. Forty-three per cent., or 43, of the cases showed mental change during the acute attack, 10 showing excitement and irritability, and 33 showing increased depression or melancholia.

Suicidal Tendencies.—In view of the importance attributed to suicidal tendencies by continental authorities, it is of interest to note that none of the 100 cases included in this series developed suicidal tendencies. This observation holds good, not only for this series of cases, but for all the cases of pellagra at Peoria.

Eye Findings.—Dr. Carroll B. Welton, of Peoria, examined the eyes of more than 50 per cent. of these cases as well as an equal number of controls, and his report on the eye changes may be found in the *Journal of the American Medical Association*, November 13, 1909.

IV. Treatment and Mortality.—The mild cases required no treatment. In the absence of marked diarrhea and constitutional depression, no treatment was required for the local erythema, which disappeared within three or four weeks. The treatment of the severe cases showing marked diarrhea and asthenia was most discouraging. Fowler's solution in increasing doses produced no noticeable improvement. Atoxyl hypodermically in 5-grain doses every seven days was administered, and in only one or two cases could improvement be attributed directly to medication. Thyroid tablets proved to be valueless. Normal saline was used in the cases of great severity with only temporary improvement. At the present time the most rational line of treatment would seem to be improvement in diet and the treatment of any complicating disease. We believe that the use of clabbered milk will prove of value in controlling the intestinal symptoms.

Twenty-two per cent. of the cases died; 10 per cent. were failing; 17 per cent. were improving; 51 per cent. recovered. An examination of Table No. 3 shows that in several of these cases sufficient cause for death was present, exclusive of pellagra, and these facts must be considered in determining the death rate in pellagra.

V. Pathology.—Laboratory Examinations; Blood. The blood findings are charted in Table No. 4. In taking blood pressure the Stanton instrument was used, the average pressure being 146. Considering the age of the patients, this was to be expected.

Hemoglobin and Blood Counts.—The hemoglobin average was 81 per cent., red cells 3,859,000, and white cells, 9,904. In 23 per cent. of the cases the white cells were normal; in 10 per cent. below normal, and in 67 per cent. there was more or less leucocytosis. Considering the condition of the teeth and intestinal tract this leucocytosis can be attribu-

ted to factors other than pellagra. It was a noticeable fact that during the acute stage of the disease with the red cell count ranging between 2,000,000 and 3,500,000, the hemoglobin estimation was almost always above 85 per cent. Differential blood counts, examination of urine and certain other examinations done by Dr. Buhlig and Mr. Holmes will appear in the Bulletin of the Illinois State Board of Health.

Negative	15.2	49.5	48.8

Feces.—Diarrhea has always been given as one of the cardinal symptoms of pellagra. This symptom was present at Peoria, and in view of our ignorance of the real nature of the disease it was thought worth while to make a microscopical examination of fresh stools. This was done in the usual way; fresh stools were collected, usually after a dose of saline cathartic, and the liquid part examined under one or two cover slips. It soon became evident that the pellagrous patients had a very high percentage of protozoal infection, and a number of non-pellagrous patients of the same general class were examined as controls. The results are given in Table No. 5. The results of a number of examinations of soldiers in the Philippine Islands under field conditions are given for comparison.

In explanation of the table it should be said that no attempt was made to differentiate between pathogenic and nonpathogenic amebæ, as such a differentiation is not regarded as practicable in clinical examination of stools; in 5 per cent. of both cases and controls the amebæ were very active and contained blood cells; in the other cases they were "resting." "Flagellates" include cercomonads and trichomonads; "encysted protozoa" include encysted flagellates and encysted amebæ and any other encysted forms. The only ova found were those of *Oxyuris* in one case among the controls. It will be readily seen that this condition is a very unusual one for a temperate climate because the patients in general had as much protozoal infection as do soldiers under field conditions in the Philippines, while the pellagrous patients had a much greater amount.

These findings are confusing in endeavoring to estimate the status of diarrhea as an essential symptom of pellagra. The few cases in which no protozoa were found had practically no intestinal disorder, while the remaining cases, showing every gradation of disturbance from a mild diarrhea to a marked and typical dysentery, had protozoal infections which could, in large part, explain the local symptoms. The possible bearing of the findings of examination of feces on the prevalence of pellagra will be considered under a discussion of epidemiology.

Autopsies.—We have records of eighteen autopsies which were usually made about 24 hours after death. A summary of the findings is given in Table No. 6; almost all the patients were senile and one-half of them showed serious concurrent diseases. The only organ which presented striking and constant lesions was the colon. In two-thirds of the cases well-marked ulcers were found, and from the findings in the stool before death and an ex-

TABLE NO. 6.—AUTOPSIES.

16	51	Sept. 19	Dr. B.	Thickened with swollen mucosa.	Negative.	Negative.	Tuberculous.

amination of sections in several cases most of these may be put down as amebic ulcerations. The ulcers were widely distributed, deep and undermined and gave the surface a "geographical" or "moth-eaten" appearance. The wall of the colon was considerably thickened and contracted in places. In one case perforation of an ulcer occurred, giving rise to an acute peritonitis. In this connection it is significant that Neusser speaks of old and recent ulcers as a finding in pellagra and another author gives perforation as an occasional cause of death. In the remaining cases a well-marked folliculitis was present and in several of these the follicles were the large preulcerative ones found in amebic colitis. The lower end of the ileum also frequently showed folliculitis.

The condition of the colon was such as to arrest one's attention, and an effort was made to find out how long it had prevailed. Autopsy records are available for the past two years. In most cases the intestines were not examined; in 12 cases they were opened, however, and in 8 of these particular mention is made of definite ulcerations. One case of multiple abscess of the liver occurred in a case with ulcerations; these facts speak for themselves.

The mesenteric lymph glands were not enlarged and the spleen was small and hard except in cases with concurrent infections.

The heart, lungs, liver, and kidneys showed no change which could be called significant. The brain in gross appearance showed only the edema of chronic dementia and the opacity of the membranes due to arteriosclerosis and old age. The cord was removed in four cases; only one case has been examined so far and it showed no degeneration of the posterolateral tracts.

VI. Epidemiology.—The failure of continental students of pellagra to agree on some definite form of the corn theory and the skepticism in some quarters of any form of this theory forced us to approach the disease with an open mind and some work was done on several different lines.

The Question of Infection.—If pellagra were an infectious disease, the infection would seem to be one of the following kinds: (1) General bacterial infection of the blood and other body fluids; (2) Local bacterial infection of the intestines. (3) Protozoal infection affecting chiefly the nervous system.

1. General bacterial infection.—Attempts at cultures, Table 4. Blood cultures were made on eight severe cases, four of whom died of the disease. In five cases, 5 c.c. of blood was drawn from a vein and incubated in 100 c.c. of glucose bouillon 48 hours and then transferred to glucose agar. In three cases 5 c.c. of blood was distributed in three tubes of bile, incubated, and transfers made. No growths of any kind occurred. The same method was applied to spinal fluid obtained by spinal punctures in eight cases; no growths occurred. Smears were made from the spleen at autopsy in five cases; no growths occurred except of colon bacilli in one case of peritonitis. It was, therefore, evident to us that no organism which will grow on ordinary media is to be found in the blood, spinal fluid, or spleen of cases of pellagra.

Examination of fresh blood and spinal fluid as well as of sections and scales of skin and of the contents of blebs were equally negative in regard to the presence of any specific organism. A number of authors have claimed that they have found organisms which they regard as specific in the blood and tissues, but we were not able to confirm any such findings.

2. Intestinal Infection.—No systematic work was done along this line, although several organisms

were isolated by plating out, and agglutinations tried without results. The clinical evidence, however, was against such an infection in the strict sense. Cases occurred in every building and no evidence could be obtained of foci of infection or transmission by contact. As mentioned before, no physicians, attendants, or employees have developed the disease. This fact seems to us most significant in giving a clue to the nature of pellagra. Persons sound in body and mind did not contract the disease, although constantly exposed to it.

3. Protozoal Infection.—The arguments in favor of the protozoal nature of pellagra have been based on analogies with sleeping sickness, kala-azar, etc. These analogies, in many respects, are not borne out by closer examination. The alleged mononuclear increase has not been found and the periodicity is of a very different nature. It should be said, however, that no attempts were made to infect animals with brain or cord pulp.

The Question of Intoxication.—Meanwhile our attention was being drawn to the intestines as a result of autopsies and examinations of the stools, and this led us more and more to the idea of an intestinal intoxication. If an exogenous or endogenous toxin was presupposed as the cause of pellagra the condition of the intestines could be easily brought into line as a predisposing factor, since the diseased mucosa would be more permeable to such a toxin. The question of food and water supply was, therefore, taken up.

Water Supply.—The water used at the institution comes from two sources: (1) An artesian well over 1,500 feet deep, which ordinarily supplies about 80 per cent. of the quantity used. (2) The Peoria water supply which ordinarily supplies about 20 per cent. of the total quantity, but occasionally is used in larger quantities. The artesian water is forced by compressed air into an enclosed surface tank, from which it is pumped to an elevated tank for pressure. The city water is pumped directly into the elevated tank.

Examination of the water was made in the usual way; examination for protozoa consisted in taking about a liter of water in a sterile flask; adding a tube full of sterile bouillon, incubating several days and examining a loop full of the scum which formed on the surface. Amebæ, flagellates, and fermenting organisms were found on each of three separate examinations of the tap water in one of the cottages.

The artesian water coming directly from the pump had something over 100 colonies to the c.c. flagellates, but no amebæ or fermenting organisms. The city water had as usual about 10 colonies to the c.c. flagellates, but no amebæ or fermenting organisms. The surface tank had no amebæ or fermenting organisms. The trouble, therefore, lay in the pipes and elevated tank, as a result of some previous contamination, possibly from the surface tank, which is not thoroughly protected; possibly from some break in the pipe system.

The amebæ in culture could not be differentiated from those in the stools; the question of their pathogenicity raises the whole amebæ problem which cannot be discussed here; but it is certainly not too much to say, especially under the local circumstances, that they should be regarded with suspicion. The same is true of the flagellates.

None of the reasons ordinarily given for the seasonal occurrence of pellagra hold good for this country, and it is not unlikely that these protozoa play a part in the seasonal periodicity of the disease. They are more active as a rule during warm weather. Summer diarrhea is a well-known complaint at Peoria; all the patients gain weight with the beginning of cold weather. The amebæ and flagellates, besides rendering the intestines more permeable to a toxin, may, by their periodical activity, predispose to the production of such a toxin.

Year	Average Number Persons Fed	Cost of Food per Day per Patient
		Cents
Ending June 30, 1906	1,725	10.0
Ending June 30, 1907	2,107	9.6
Ending June 30, 1908	2,147	11.4
Ending June 30, 1909	2,200	15.5

Food Supply.—The preceding table shows the average daily cost of food for each patient for the last four years.

The increase in the last year has been largely due to the cost of special food for consumptives. The other figures are a trifle lower than those for the other principal insane asylums of the State.

Due care seems to be taken in the purchase and handling of the food stuffs, and their preparation is under the supervision of a special dietitian. All the food is prepared in a central kitchen and distributed to the cottages by carts and wagons in covered receivers. Five diets are prepared for each meal, according to a bill of fare made out the previous day. (Table No. 8.) (1) General diet for the majority of the patients. (2) Light diet for patients in hospital. (3) Milk and egg diet for consumptives. (4) Special diet for infirm patients. (5) Diet for attendants. It will be seen that the diets are good as institutions go. The daily food in the general diet averages about 2,000-2,500 calories, which is made up approximately of 30 gms. proteid; 70-80 gms. fat and 300-400 gms. carbohydrates. Meat is given only twice a week. On the whole, it may be said that the food supply is satisfactory except that the general diet is somewhat deficient in proteids.

Granting that some damage to the intestines was a predisposing factor in an intoxication in a majority of cases, what was the specific toxin which produced the erythema, stomatitis, and debility? This leads us to the question of corn and the overwhelming consensus of opinion among those most concerned that corn is, in some way, responsible, is not lightly to be cast aside.

The following table shows the amount of principal corn products received:

TABLE SHOWING AMOUNT OF CORN PRODUCTS CONSUMED.

Corn Products	1907	1908
Corn Meal	31,200 lbs.	30,100 lbs.
Hominy	17,400 lbs.	14,500 lbs.
Corn Starch	1,420 lbs.	1,296 lbs.
Corn Flakes	3,912 lbs.	2,760 lbs.
	53,932 lbs.	48,656 lbs.
Population fed	2,107	2,147
Amount per year per patient	416 oz.	352 oz.
Amount per day per patient	1.1 oz.	.9 oz.

The patients on the general diet received rather more than the average for the whole population, but not to exceed an average of 2 ounces a day.

The possible relations of corn to the disease seem to be the following: 1. Good corn may be injurious in large quantities. This theory can hardly be used to explain the trouble at Peoria, in view of the amount eaten as given above. It has been estimated that about 16 ounces of uncured rice per day are necessary to product beriberi. For corn to hold the same relation to this disease, a much larger amount would have been necessary at Peoria.

2. Spoiled corn may be responsible; this was not the case so far as could be ascertained by the senses. The corn used was inspected on the corn exchange and at the mill, and it was No. 2, the best on the market. Nothing in the way of a "food scandal" could be unearthed. The corn meal was freshly ground, and the other corn products did not have to be transported any great distance. None of the corn products were spoiled in the sense of being mouldy, damp, hot or of bad odor or taste.

3. Toxins may be developed in the intestines by the action of fungi or bacteria on a corn diet. In regard to moulds, several trials were made, but no moulds were found which survived the heat of cooking. Of course this does not exclude them, but it makes them seem less likely as a cause. On the other hand, a spore-bearing bacterium was repeatedly found in corn meal and hominy which survived steaming for two hours, and seems to offer possibilities. This is a motile, sporé-bearing, gram positive, nonliquefying bacillus which produces a red coloration on corn and an odor like that of rancid fat.

In order to learn something of parasites on corn, a trip was made to the University of Illinois, and it was found that only in recent years has any definite work been done on this subject, and that much remains to be done, especially in regard to bacteria.

The organism mentioned above is apparently referred to by Burrill and Barrett (Bull. 133, University of Illinois, Urbana station, 1909, pp. 91-92), as causing disease of corn in the field. "Certain ears when stripped of the husks show grains which are evidently diseased, rather uniformly distributed among the sound kernels or in small groups on some part of the ear. The diseased kernels are dark in color, often corroded upon the surface, and are brittle in texture. Sometimes a shiny, mucilaginous orgum-like exudate is noticeable upon the outer surface of the grains. Upon microscopical examination, this exudate is found to be made up of pure culture of a medium-sized bacillus of short cylindrical shape and capable of rapid ciliate movement. These are present in myriads and what appears to be the same organism is found in great numbers in the crumbling, starchy portions of the affected grains. A conspicuous characteristic of such diseased kernels is the red color taken by the substance of the scutellum. When such grains are divided lengthwise through the flat surfaces the starchy portion is seen to be distinctly white, while that known as the chit is as distinctly red. The infection seems to begin externally with the silk and the bacteria follow a strand of this to its attached kernel, explaining how it comes about that any one of the latter upon the cob may be diseased among adjoining healthy ones. Where these bacteria otherwise live has not been ascertained. The bacteria of the corn-growing plant is a subject well worth special study."

The most common cause for disease of ears on the stalk has been found to be a kind of *Diplodia,* which has been stated by one author to be on the increase in recent years, and along with aspergillus, penicillium, etc., has been advanced as a cause of pellagra. The department of botany has furnished us cultures of known moulds and bacteria, and work is being done with these.

The most promising field for investigation seems to be along the line of an intoxication produced by bacterial action on corn products and possibly other carbohydrates in a damaged intestine, and this will be followed up. Several instances have come to our notice of a toxic action for animals, first of an excessive corn diet, also of a diet of corn gluten infected with moulds; and there are no doubt several kinds of disease connected, in some way, with corn, but pellagra, if associated with corn, must be due to one, not to several, kinds of corn poisoning.

The outstanding facts about corn raising in the last fifteen years are, that the shelled corn is marketed four to eight weeks earlier than it used to be, that the time of weathering and drying on the stalk

is cut short, and that more trouble is experienced in handling the corn and preventing it from going bad. These facts, together with the considerable increase of the use of corn products in the past few years, may prove to be of significance.

The recommendations respectfully submitted for the Peoria State Hospital were: (1) Cleaning out the pipes of the cold water supply; better protection of the surface tank; regular examinations of the water for bacteria and protozoa; examination of stools of possible cases of dysentery, especially among the untidy, and appropriate treatment of dysentery cases. (2) Elimination of corn from the diet of the pellagrous and more debilitated patients, and continued care in the purchase of corn products.

Use of Corn Products in the Army.—Statistics obtained from the Purchasing Commissary in New York show that the proportion of corn to wheat purchases is only 1 to 100, and that nearly all of the corn meal purchased is kiln dried. Samples of kiln-dried meal have been examined, and showed very few organisms of any kind, while freshly milled corn meal contains an abundance of various kinds of organisms. In Italy the drying of corn has been adopted by the government as a prophylactic measure. At present we would recommend that the purchase of kiln-dried meal be continued, and that any other types of meal purchased be freshly milled and made of the best No. 2 corn. No corn should be used in the diet of the sick suffering from intestinal diseases.

VII. Summary.—1. Of 2,150 inmates at the Peoria institution, the majority of whom have been almshouse and asylum inmates for many years, 175 were pellagrous during the summer of 1909. No physicians, attendants, or employees were affected.

2. About 70 per cent. of cases had suffered from previous attacks and pellagra has been prevalent at least four years.

3. The average age of cases was 50 years; the sex distribution was about equal.

4. Attacks were mild (skin symptoms, mild digestive tract symptoms without constitutional reaction) and severe (marked skin and digestive tract symptoms with pronounced toxemia).

5. A diagnosis of pellagra is not warranted in absence of skin symptoms. The symmetry of skin lesions was a most striking feature. When bleb formation occurred the death rate was high.

6. Digestive tract symptoms were not present in all cases. In some cases diarrhea and stomatitis could be attributed to bad teeth, and infection with amebæ and flagellates, but in other cases, the constitutional symptoms pointed to some additional specific poison.

7. Patellar and plantar reflexes were abnormal in about three-fourths of the cases, usually increased.

8. It was impossible to determine the exact extent of mental disturbance attributable to pellagra, as all patients were insane before the disease was recognized. The cases developed no suicidal tendencies.

9. Mild cases recovered without therapeutic aid. Severe cases were not much benefited by Fowler's solution, atoxyl, or thyroid tablets.

10. Feces; 84.8 per cent. cases showed protozoal infection (amebæ flagellate and encysted forms). These protozoal infections account in part for the intestinal symptoms and are believed to be a predisposing factor.

11. In 18 autopsies, well-marked ulcerations of the colon were found in 12 cases, and folliculitis occurred in all. No other organ showed any constant or striking alteration.

12. Cultures of blood, spinal fluid, and spleen pulp were uniformly negative.

13. The disease impressed us as an intoxication rather than an infection.

14. Not more than two ounces of corn were eaten per day; no evidence was obtained of the use of spoiled corn.

15. The possibility of an intoxication from bacterial action on corn products in a damaged intestine is considered the most promising field for study.

A PRACTICAL METHOD OF OBTAINING THE DUODENAL CONTENTS IN MAN.*

By MAX EINHORN, M.D.,

NEW YORK.

PROFESSOR OF MEDICINE AT THE NEW YORK POSTGRADUATE MEDICAL SCHOOL.

The importance of testing the duodenal contents is evidently great. Here we find the most important secretions for digestion. The duodenal bucket[1] occasionally brings up the desired juice, but the same may be mixed with stomach contents, and its quantity is too small to make more detailed examinations. The aspiration catheter[2] which I introduced later over the thread of the duodenal bucket beyond the pylorus, into the duodenum, has also not quite succeeded in solving this problem. The introduction of the catheter is somewhat difficult, and it can be introduced only into the pylorus and the beginning of the duodenum, but not into the lower portions of the duodenum.

I have therefore constructed a new instrument for this purpose. It consists of a small metal capsule (14 mm. long and 23 mm. in circumference), which is perforated and can be unscrewed. This communicates with a long, thin rubber tube (8 mm. circumference and one meter long), and is marked at 40 (I. cardia), 56 (II. pylorus), 70 (III.), and 80 cm. distance from the capsule. At its end is a tip, to which a syringe can be attached (Fig. 1). This small instrument looks almost like the deglutable electrode. It can be used for aspirating stomach or duodenal contents, and might aptly be called a "duodenal pump" or "digestive juice aspirator."

Mode of Procedure.—The capsule of the duodenal pump, as well as the lower part of the rubber tube, are moistened with warm water and put into the pharynx of the patient. Then the latter drinks some water, and the instrument thus soon passes into the stomach. To be certain that the capsule did not get stuck in the esophagus, it is well to have the patient shake his abdomen and to aspirate a syringeful of chyme. This can easily be identified as gastric contents. Now we pass a syringeful of water and then one of air through the instrument. The rubber tube is then clamped off and left alone for about one hour. The patient is told not to close his mouth too tightly, so that the tube is not retarded in its wanderings. The patient must also avoid intentional swallowing of the tube. Through the peristalsis of the stomach the capsule is pushed on further, and usually passes through the pylorus into the duodenum and later into the beginning of the small intestine. It is best to have the patient read some light literature, in order to divert his attention.

*Read before the Clinical Society of the German Hospital and dispensary, November 11, 1909.

After one hour we examine how far the capsule has progressed; if sign III is near the lips (70 ctm.) or inside the mouth, we try to aspirate. If the capsule is in the duodenum, we generally obtain a clear, golden yellow or watery liquid of alkaline reaction and somewhat viscid consistency. If, however, we

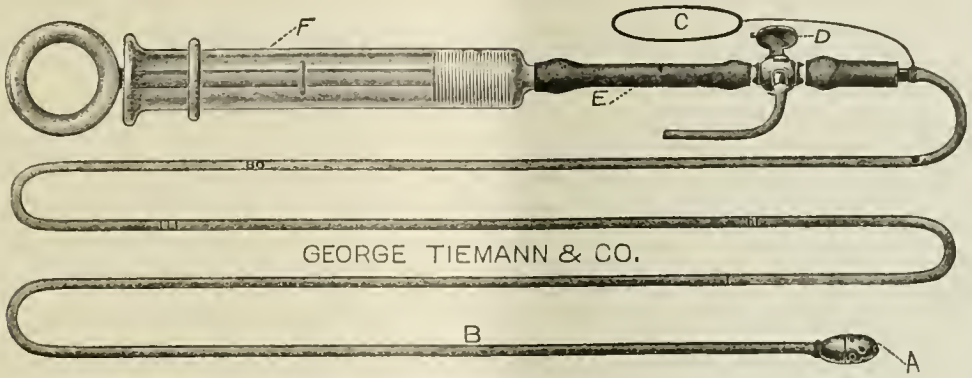

FIG. 1.—The Duodenal Pump. A, metal capsule, lower half provided with numerous holes; the upper half communicating with tube B; I, II, III, marks of I=40, II=56, III=70 ctm. from capsule; C, rubber hand with silk attached to end of tubing, which can be placed over the ear of patient; F, aspirating syringe; E, collapsible connecting tube; D, three-way stopcock.

are in the stomach, we obtain an acid liquid resembling the one first removed. This can, of course, occur if the tube lies in the stomach in a coiled manner, as the accompanying *x*-ray picture shows (Fig. 2). Should the latter be the case, we must partly

FIG. 2.—*X*-ray photograph of Miss H. lying with her abdomen on the plate, with the duodenal pump in the stomach. The tube is curled up and describes the shape of 8.

withdraw the tube, after putting water and air through it, up to the mark II (56 ctm.). The tube is then again clamped off, and after one-half to one hour the procedure is repeated. We generally succeed in nearly all cases (of course, not in such where there is pyloric stenosis) to obtain duodenal contents. After having obtained the desired contents, the tube is clamped and slowly withdrawn. When the beginning of the esophagus is reached the patient is told to swallow, and during this act the capsule is withdrawn.

The same instrument can, of course, also be used to study the act of gastric secretion during the entire period of stomach digestion from beginning to end. In this case the tube is fastened so that it cannot go beyond mark II; the capsule thus remains all the time in the stomach. Every half-hour or so the contents may be aspirated and comparisons of the acidity, etc., made, and thus the secretion of the stomach may be studied.

In examining the contents of the duodenum it is of importance to have evidence when we are in the stomach and when we are in the duodenum. I therefore wish to call attention to the following points:

1. If the capsule is in the stomach and we aspirate, the syringe quickly fills with fluid or air, provided that the holes are not clogged by thick food. The heavier rubber tube attached to the syringe does not collapse, as this organ is always filled with either air or liquid. If, however, the capsule is in the duodenum, one finds that the connecting rubber tube will collapse on rapid aspiration. This is caused by a vacuum forming, owing to the fact that there is not much air or liquid in the duodenum and because the walls of the latter are in close apposition to the capsule. (We find the same condition if the capsule is in the esophagus.) After waiting a short while and after slowly trying aspiration, fluid enters the syringe. If we find a larger supply of bile and pancreatic juice, it appears a little quicker, but always slower than from the stomach.

2. If the capsule is in the stomach and air is forced through, the patient feels the entrance of the air very plainly and can localize where it occurred. If the capsule is in the duodenum or jejunum, the patient does not usually feel the entrance of air.

3. The milk test. If we give patient two or three swallows of milk (provided, of course, that no milk had been previously taken), and then aspirate with the capsule in the duodenum, we obtain pure duodenal contents (golden yellow or clear as water) without any admixture of milk. If, however, the capsule is in the stomach, the milk appears at once. This milk test can be made still more reliable if, after aspiration of clear duodenal contents free from milk, we withdraw the tube up to mark II

Fig. 3.—X-ray photograph of Miss H. lying with her abdomen on the plate, with the duodenal pump in the digestive tract. The tube is seen to extend through the fundus and greater curvature of the stomach, also through the pylorus and the entire ring of the duodenum.

and a little further, and on renewed aspiration obtain the fluid from the stomach, containing unchanged or curdled milk.

4. The *x*-rays show the position of the capsule in the stomach or duodenum very plainly. A good apparatus shows not only the capsule, but also the course of the tube (Figs. 3 and 4).*

Preparation of the patient for the purpose of duodenal examination. It is best that the patient should take only fluid food on the day of examination. In most cases I have had him take a cup of tea and sugar without milk half an hour before the examination. Of many cases tested I will cite two as examples:

Case I.—Nov. 7, 1909. Mrs. R., 8:15 A. M., swallows the duodenal pump half hour after tea and sugar; 9 A. M., tube has gone down to 75 ctm. Upon aspiration a yellowish liquid appears, reaction alkaline. One hour later milk is given. On aspiration some more yellowish alkaline liquid is removed. The tube is then withdrawn into the stomach and a yellowish milky liquid is obtained, which reacts slightly acid.

Case II.—December 5, 1909. Harry Z. swallows half hour after tea and sugar, the duodenal pump. One hour later gastric aspiration shows a liquid containing traces of HCl. One hour and one-half hour later tube is 75 ctm. down and aspiration reveals a yellowish pancreatic secretion, alkaline, specific gravity 1003, about 6 c.c. steapsin, + slice of egg albumen nearly all gone; diastase +. Patient drinks milk and then aspiration is again practised. Again we obtain clear golden yellow liquid of alkaline reaction. The tube is then withdrawn beyond the mark II, and aspiration reveals a milky acid fluid.

*I am indebted to Dr. L. G. Cole for the excellent *x*-ray photographs.

Examination of duodenal contents. After inspection the reaction is tested with litmus paper. Usually the reaction is faintly alkaline. We have, however, exceptions to this rule, and I have occasionally obtained slightly acid contents, and twice I have found a positive HCl reaction in positively duodenal contents that contained bile. Then we make the test for the ferments (a) steapsin, (b) trypsin, (c) amylopsin.

(*a*) To test for steapsin I use a drop of neutral milk, two drops of water, two to three drops of duodenal contents (neutralized if the reaction is acid), and a small piece of blue litmus agar. This is placed into a miniature test tube and kept at blood temperature. If steapsin is present the agar piece will be red in twenty to thirty minutes, owing to the development of fatty acids.

(*b*) For the demonstration of trypsin I use a small piece of the white of a hard boiled egg, which is placed in the fluid to be examined (if acid, it is first neutralized) and kept a few hours at blood temperature. The piece of egg albumen disappears in the presence of trypsin. The ricin test used for pepsin is unsuitable for trypsin. If we add ricin solution to duodenal contents and leave it at blood temperature for a few hours, and then add hydrochloric or acetic acid, the ricin will often be precipitated, *i. e.* it was not changed into soluble peptone.

(*c*) Amylopsin. For testing for the presence of diastase we make use of a boiled starch solution or starch paper. We mix the duodenal contents with the starch solution (in equal parts), or insert a strip of starch test paper and leave it at blood temperature. After half to one hour we look whether the

Fig. 4.—Same as Fig. 3, after the ingestion of bismuth into the stomach. The shape of the stomach is distinctly visible, and outside of the stomach in the duodenum are seen the tube, describing the shape of this organ, and at its end the capsule.

fluid or the test paper contains starch by adding a weak iodine solution. In the presence of starch we obtain a blue color, in the presence of erythrodextrin a red color, otherwise only a trace of brown from the iodine.

SOME EYE TROUBLES OF EARLY LIFE.*

FOR THE GENERAL PRACTITIONER.

By JOHN WAITE AVERY, A.B., M.D.,

NEW YORK

INSTRUCTOR IN DISEASES OF THE EYE, NEW YORK POST-GRADUATE MEDICAL SCHOOL, ASSISTANT SURGEON, NEW YORK THROAT, NOSE AND LUNG HOSPITAL, FELLOW, NEW YORK ACADEMY OF MEDICINE, ETC.

I SHALL limit this discussion to the refractive and muscular disturbances of the eye from infancy to youth. As introductory to this permit me to review briefly the refractive conditions of the normal and abnormal eye.

In the normal or emmetropic eye the dimensions are such, and the refractive media of that shape, size, and consistency, that parallel rays proceeding from infinity, or a distance of twenty feet or more, focus clearly upon the retina, with the accommodative apparatus in a state of absolute rest (See Fig. 1). The image of an object at less than twenty feet is made distinct upon the retina of a normal eye only with the aid of the apparatus of accommodation, which consists of the ciliary muscle, the lens, and the ligament or zonula of Zinn, which suspends the latter. Contraction and expansion of the three sets of fibers of the ciliary muscle are transmitted through the zonula of Zinn to effect change in the shape of the lens. Rays from objects within infinity are too divergent as they enter the eye. By this mechanism of accommodation they are so bent as to be received clearly upon the retina. The brain will not tolerate

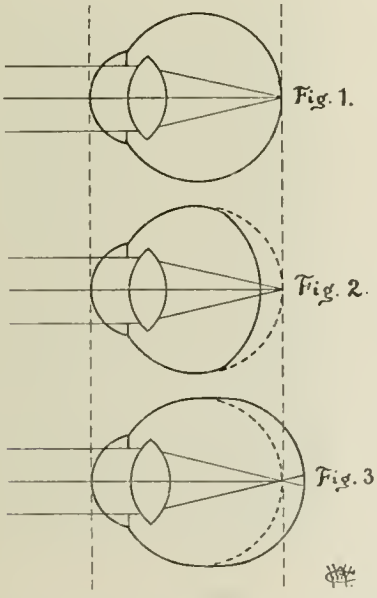

Fig. 1.

Fig. 2.

Fig. 3.

an indistinct image, and summons this apparatus which instantly responds to correct the defect. This is the operation of the emmetropic eye in far and near vision.

Unfortunately, most children are not ushered into life with a pair of eyes in this ideal condition. The eyeball of the infant usually has an anteroposterior diameter too short for the refractive power of the media. Parallel rays entering such an eye from infinity focus not on its retina, but theoretically at a point behind it. Only a blurred image is received

FIG. 4.

upon this retina—really a truncated cone of rays whose apex is the principal focus behind this plane. Much more indistinct must be the image of objects within infinity, and the greater is the demand made upon accommodation to bend these divergent rays—a strain in direct proportion to the nearness of the object and the shortness of the globe horizontally. This condition we know as hyperopia, or far sight. (See Fig. 2). Later, as the child develops, the eyeballs should assume the proportions of emmetropia, and hyperopia should disappear. Sometimes this fails to occur in whole or in part, leaving a permanent hyperopia of greater or less degree.

Again, through congenital defect, or overdevelopment, the globe has an excessive horizontal diameter, or an increase in the refractive power of the media. In an eye containing either or both of these conditions the parallel rays reach a focus in front of the retina in the vitreous, with the result that it again receives only a blurred image from these diverging rays. (See Fig. 3). This is myopia, or short sight, and is rare in early life.

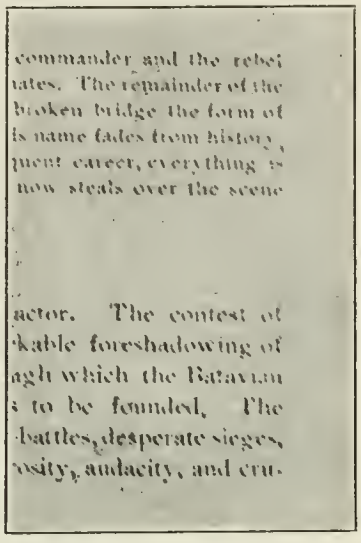
Another frequent imperfection is that in which parallel rays are not brought to a common focus in any one point on the retina. Through irregular curvature of the cornea and other refractive media we have foci of varying lengths in two or more different meridians, with the result that the retina receives an irregular picture. We term this astigmatism, in which is found another and serious hindrance to perfect vision. The effect of even small degrees of astigmatism is forcibly illustrated by placing cylinders before the exposed photographic plate, thereby producing an artificial astigmatism. Fig. 4 represents the image received by a normal or emmetropic eye. The blurring of Fig. 5 is due to only a + .25 cylinder, and the confused characters of Fig. 6 are made by a + .50 cylinder.

With one meridian normal, or emmetropic, in length, and that at right angles shorter, or hyperopic, we have simple hyperopic astigmatism. Or two opposite meridians may be of unequal length, and both shorter than normal, making a compound hyperopic astigmatism. In the same manner abnormally long and unequal diameters may produce myopic astigmatism, simple and compound. Also

*Read before the Stamford (Conn.) Medical Association.

with two meridians, one longer and the other shorter than the normal, we may have a mixed astigmatism.

Still other errors in vision may be due to muscular imbalance, in which are concerned the six muscles attached to each eye-ball, namely: The superior, inferior, external, and internal recti, and the superior



commander and the rebel
tates. The remainder of the

and inferior obliques. It is only by the most perfect adjustment of this external apparatus that these two sets of muscles act in coordination and produce binocular vision. The minute lengthening or shortening of a muscle by an irregular attachment, or the abnormal increase or decrease in power of one muscle, or set of muscles, are among the common factors of imbalance. An illustration of the latter cause is the pair of eyes with the external recti equal in strength to the interni, whereas they should have only about one-third of that power, convergence, the function of the interni, being more necessary than divergence. These conditions all impose an extra strain on the young and immature nervous system.

I have thus stated these primary principles to more strongly emphasize the fact of the handicap with which many a child begins life. Claibourne sets forth the relation of early eye strain to these unfortunate social conditions in the following forcible words: "The causes of eye strain in children are found in refractive and muscular irregularities, in the unhygienic and badly illuminated school and study rooms, and in the silly and unreasonable demands made on the brain and nervous system of the children of this generation by parents and educators. At the very age when the tissues are most yielding and soft, and the whole nervous system is tingling with new and unanalyzed sensations, before experience has had opportunity to teach the value of economy of time and effort, mental and nervous loads are put on our children, which could not be borne under the most ideal conditions."

The symptom complex of eye strain includes a wide variety of conditions and complaints, many of which are seemingly remote from the cause, and are traced to it only after failures in treatment, and by a process of elimination in the diagnosis. Errors of refraction may give the small child no trouble whatever until he starts to school, when begins the first severe test of his accommodation. After a time the lid margins may become a little red, and fringed with fine branny scales and the conjunctivæ slightly injected. If this condition is neglected an exaggeration of these symptoms may appear in deeply red somewhat swollen lid borders whose edges are stuck together in the morning, some watering of the eyes, squinting, and occasional headaches. His face may assume an anxious expression, his brow be knitted, motions nervous and somewhat uncertain, and his features grimaced at times. Inattention may mark his course at school, and punishment from zealous teachers and disappointed ambitious parents has a discouraging mental and moral effect on the little victim. No doubt that many a mediocre career is thus begun, which with the recognition of the cause and removal of the same, might have been one of great usefulness and perhaps brilliance.

Headaches are probably the most common complaint from eye strain. These are usually supraorbital or temporal, but may be occipital, or even referred to the mastoid region. They are of a dull character, rather than a sharp pain, and may be felt early in the day and more or less continuously, or appear only after close application. There may also be aching in the eyeballs and redness of same after prolonged near work. Restlessness, peevishness, irritability, lassitude, cold extremities, are all sometime symptoms of eye disturbances.

The face and general appearance of many of these patients is interesting and suggestive. The hyperopic child may be painfully anxious and nervous in manner, his face older than his years and careworn. This may be the only outward indication of a severe nerve strain from which he suffers in overcoming the eye defect, in which he succeeds, but at a terrible cost. Contrasted with him is the typical myope whose face may be rather dull and apathetic, his motions slow and cautious, and he manifests little or no interest in the amusements of his playmates, but may be found at any or all hours absorbed in his books. This patient has partially given up the struggle with poor vision. He has found that he cannot improve it by straining, that sports or

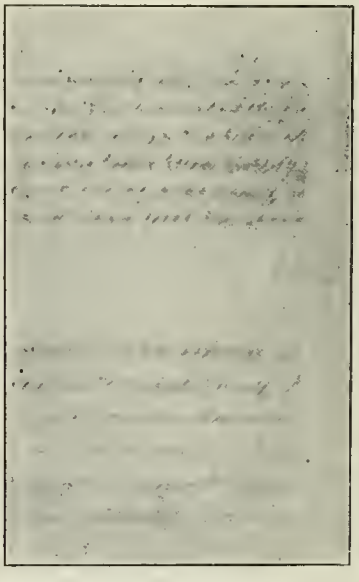

Fig. 6.

occupations requiring far and quick sight are impossible, and so he turns naturally to those employments in which his near vision is most useful. His compensation is a relief from the nerve strain which the successfully seeing hyperope endures.

Purely reflex disturbances are manifest in many

ways and may simulate, among others, diseases of the gastrointestinal tract and disorders of the nervous system. Dr. S. Weir Mitchell in 1876 made a profound impression by publishing his observations upon a large number of cases of nerve disorders which he found to depend largely if not wholly upon abnormal eyes. His insistence upon eye examination and treatment was probably more regarded by the profession at large because it came from an eminent neurologist rather than from an oculist. Abdominal pains and functional disorders of the digestive tract are emphasized by Dr. Gould as sometimes being symptoms of ocular strain. An unusual case of this class was reported by Dr. Ellice M. Alger of New York in 1907. A boy had severe intermittent abdominal pains for several months. The diagnosis of a local surgeon was appendicitis, and of another cholelithiasis. However, operation was refused by Dr. Robert T. Morris of New York until the factor of eye strain should be eliminated by refraction. He had normal vision in both eyes without glasses, complained of no headache or eye pain. Under atropine the total error was found to be small, and the wearing of a +° .75c., ax. 90° lieved all the symptoms.

A recent case of mine further illustrates this point. D. T., age 15, school girl, had "bilious" attacks for four years, and was lately having two or three a week. She complained of some pain in her eyes, and headaches especially during the attacks, which were most frequent late in the day. She gave a history of slight rheumatism. Menses began at age of eleven and are normal. Two months general treatment, including both medicine and diet, had failed to relieve the condition and these attacks continued as before. Examination of the eyes was negative as regards disease, and her vision was 20/20, or normal. With atropine the vision was only 5/20c in each eye. The refractive error was simple hyperopic astigmatism in the right eye, and simple hyperopia in the left. At the time of the atropine examination she stated that her eyes felt much better with the drops in them, while headache and tendency to nausea had disappeared. This was striking proof of the reflex effect of eye strain and of how quickly some of these patients are relieved. Since wearing the correction she has had no return of the old trouble, except when for two days she was, through accident, without her glasses. At this time she had slight headache and nausea.

Another case in point is that of a girl seven years of age with fair general health. No eye trouble before starting to school, which was only recently. Soon after beginning school work her eyelid borders showed irritation and were scaly in the morning. She sometimes complained of them being tired and had trouble in seeing the blackboard and some headache. Her vision was 20/20 in each eye, but under atropine was only 20/70 in the right eye, and 20/100 in the left. This proved to be a simple hyperopic astigmatism of low degree, and all trouble disappeared after she wore the correct glasses in school for a short time.

Cases of muscular imbalance with marked subjective symptoms are more common among children when they reach the upper grammer grades and high school, where the work is more exacting, and the hours of application are longer. Such a patient was M. D., age 15, who gave a history of severe headaches for past two years, especially in the left eye. Glasses previously given had afforded partial relief, but the symptoms of eye strain would still return. Her face wore an expression of great anxiety, brows were deeply knitted, and there was some photophobia and lacrymation besides much general nervousness. Vision was about normal in both eyes, but they quickly tired in examination, and could be tested only a short time at each sitting. The vertical muscular balance I found much impaired, the line of vision of the left eye being some 2½ degrees higher than the right. This we consider excessive, as even ½ to 1 degree of vertical deviation will often cause much disturbance. The strength of adduction compared with abduction was as 4 to 3, instead of at least 12 to 3. Her vision under atropine was 20/50 right and 20/40 left eye, and was brought to normal, or 20/20, with a weak plus cylinder. Subsequently she required prism exercises, which with this correction relieved the muscular strain, and she improved greatly.

A most interesting class of cases are the children with squint. Strabismus, or squint, is that condition in which the visual axis of one eye is deviated from the point of fixation. It is the result of two conditions: "A diminution of the visual power of one of the eyes, and a preexisting disturbance of the muscular equilibrium." Convergent strabismus occurs partiularly in hyperopia, which Fuchs states is found in about three-fourths of all these cases. The reason for this lies in the strong accommodative effort which the farsighted person must make to obtain clear vision, and in the intimate connection between convergence and accommodation. It develops usually at the age when fixation begins to make greater demands upon accommodation, that is from two to six years of age. Conditions which favor its development are: diseases of infancy which have produced opacities of the cornea, such as ulcerations complicating ophthalmia neonatorum, eczematous conjunctivitis, congenital poor sight or amblyopia, prolonged bandaging of one eye, and large refractive error in one eye only. Divergent strabismus is related to myopia much as hyperopia is to convergent strabismus. About two-thirds of these patients are nearsighted. It is favored by the difficulty the myope naturally has in accommodating. As the elongated eyeball is but rarely found in infancy, so divergent strabismus is not a condition of this early period, but develops with myopia during youth or later even. The very early treatment of the hyperopia in convergent strabismus is not only the logical but the practical course to pursue. While many still ridicule the idea of putting glasses on a child two to four years of age, it has been successfully done. Worth of London, among others, has written most convincingly in connection with a large number of cases reported cured. It is reasonable to believe that the time to begin this treatment is while the squint is still intermittent, or "periodic," and before the sight has been damaged. Operative treatment certainly should not be attempted before a long trial with glasses has been made, and some believe that ten years is the earliest age for a tenotomy. We can expect to cure, or even to assist a divergent squint only by operation. In recent periodic cases, the outcome may be good, but in those of long standing, and with high degrees of myopia, we can hope only for cosmetic results.

In closing I wish to emphasize the use of a thoroughly reliable cycloplegic in refracting children and youth. We have seen how active and powerful the accomodative apparatus is at this period of life and from cases cited that only by a complete paralysis of these muscles can we discover the kind and

extent of error that exists. With many others I have tested the various drugs for this purpose, and agree with the almost universal conclusion that for absolute accuracy atropine sulphate in weak solution, grains 2 to 4 in 1 oz., is the cycloplegic *par excellence*. It must be instilled three times a day for a period of three days, and sometimes more, to thoroughly prepare the eye for examination. Many parents hesitate at this, both because of the popular prejudice to belladonna and well intended but misguided sympathy for the child who must go blindly stumbling about for ten to twelve days. Here the family physician can render both his patient and the oculist a valuable service by emphasizing the absolute necessity for this treatment, and by reassuring them of the harmlessness of those transient symptoms which sometimes appear in the use of this drug.

To summarize, we have stated that:

1. The infant eyeball is usually too short anteroposteriorly, or hyperopic, for the refracting apparatus.
2. This diameter may rarely be too long or myopic.
3. The diameters may vary in different meridians, astigmatism, even small degrees of which can cause serious disturbance.
4. The resulting blurred retinal images from these causes are made and kept clear only by the constant action of the muscles of accommodation.
5. Imbalance of the extraocular muscles can result in much trouble.
6. These conditions may give no especial trouble, or even become apparent, until the strain on accommodation begins when the child starts to school.
7. They may prove to be an early and increasing handicap to the child.
8. Headaches are a common symptom of eye strain and disorders of the lids and conjunctiva are not unusual.
9. Remote reflex disturbances, such as nervous, gastric, and intestinal troubles, may have the same origin.
10. The fact of error of refraction, and its amount, may not appear without a cycloplegic.
11. Complete and rapid relief often follows careful correction of refractive and muscular imperfections.
12. These should receive prompt attention when first noted or suspected.
13. Atropine sulphate should be used in making these examinations of children and youth.

THE INTERPRETATION OF CLINICAL HEARING TESTS ACCORDING TO THE AUTHOR'S SENSITIVE HAIR THEORY OF SOUND PERCEPTION.*

By W. SOHIER BRYANT, A.M., M.D.,
NEW YORK.

The interpretation of the results of hearing tests according to the author's sensitive hair theory of undifferentiated cochlear tone perception corresponds under most conditions to the generally accepted interpretations of these tests: For example, the interpretation and explanation of the tests for middle ear impairment and for nerve, cerebral, and cortical impairment of the cochlear nerve tract are unchanged. Upon the author's theory, however, the interpretation of clinical hearing tests differs in the cases of lowered high tone perception dependent upon cochlear lesions, *i. e.* lesions of the structures in the scala media. In this paper, the author will consider losses in high tone perception due to cochlear lesions alone.

Briefly stated, the author's sensitive hair theory of undifferentiated cochlear tone perception is: A sound wave, after it has been transmitted through the external and middle ear, and has entered the labyrinthine fluid, beats upon the sensitive hairs of Corti's organ. These sensitive hairs appear to the the author to be the means of the transmission of the sound wave impulses to the neuroepithelial cells. The sound waves pass over these sensitive hairs in much the same way as wind waves pass over a corn field. The motion of the hairs thus caused is transmitted down the hairs to the neuroepithelial hair cells of Corti's organ, which transform the sinus sound waves into a nerve motion, and the perception takes place in the higher centers of the brain, the sound waves not being analyzed in the cochlea as is generally supposed.

This sensitive hair theory of the undifferentiated tone perception is based on the phylogenetic and ontogenetic development and upon the author's histological findings of the structure of the organ of Corti.

The question as to whether this theory of the undifferentiated tone perception by means of the sensitive hairs will fulfill the acoustic requirements, is answered in the affirmative for the following reason: Every property of the sound wave is represented in the form of the wave and is expressed in the character of the wave form. Every character of the wave form is imprinted upon the sensitive hairs of the neuroepithelium of the organ of Corti. The neuroepithelium transforms the molecular sound vibrations into nerve impulses. The perception of tone depends upon the power of the brain to interpret the stimulus transmitted by the cochlear nerve.

Our histological observations have proved to us that the most delicate part of the cochlear mechanism is the sensitive hairs. This is shown by the fact that in all manipulations for the purpose of studying the histology of this organ, these hairs are largely destroyed and, before any other structure of the cochlea is affected, injury to the hairs is caused either by the manipulations or by the reagents used. These hairs, therefore, are most likely to suffer the first injury in disturbances of the scala media.

Besides being the most destructible structure of the terminal organ, the hair-band is also the most highly specialized portion of the cochlea, as shown by its phylogenetic and ontogenetic development. The mechanical structure, too, shows the specialization of the hair-band, since this hair-band is admirably adapted mechanically to feel the fine vibrations of the high tone sinus waves. The physical form of this hair-band—long elastic filaments—indicates a sensitiveness to molecular movement unsurpassed by any other structure of the body. Any interference with the terminal mechanism must, of necessity, interfere first with the perception of the highest tones, since the alteration in the mechanism would first disturb the fine adjustment of the sensitive hairs of the mechanism required for the transmission of the highest note-waves. Thus

*Read at the Sixteenth International Medical Congress and the Eighth International Congress of Otology, Budapest, August 29-September 4, 1909.

we explain why the high tones are lost first instead of the lower tones, or both at the same time.

In extent, the loss of high tone perception must be in proportion to the gravity of the lesion causing the interference of the transmission of the wave impulse from the endolymph to the cochlear nerve endings. The author believes that this impairment of auditory function must extend downward from the top of the scale, for the reason that the most delicate part—the part which transmits the highest tones—suffers first under abnormal conditions.

According to the author's theory, a localized lesion of the cochlear mechanism causes only a quantitative impairment of tone perception. A localized lesion cannot affect the qualitative tone perception, since the unaffected parts of the mechanism would still perform their function. A local lesion causes an interference with the transmission of stimuli from the affected part of the cochlea. This interference results in a lessening of the sum total of the stimuli which reaches the brain, and therefore results in a lessening of the sum total of the tone impression. The sum total of the stimulation of the auditory center is lessened in proportion to the area of Corti's organ which has ceased to functionate. Since a localized lesion could only cause a quantitative and not a qualitative perception of tone, it is the theory of the author that the lesion must be diffuse in order to destroy the perception of the higher notes.

Conclusion. In diseases of the cochlea, when there is only a quantitative impairment and not loss of high tone perception, the author maintains that the lesions of the cochlea must be localized. When, however, there is a total loss of perception of high tones from cochlear involvement, the author interprets this absence of high tone perception as due to a lesion which is diffused throughout the extent of the scala media.

41 East Thirty-third Street.

Asiatic Cholera.—Nichols and Andrews conclude a paper on this subject as follows: (1) With regard to sex and age, cholera occurred in proportion to the population, with an excess of cases in children under ten years. (2) Intravenous injection saved about 80 per cent. of the cases from collapse. (3) Nearly half of those who survived the stage of collapse showed some symptoms of uremia, and nearly one-third died of this complication. (4) In general, the intravenous injection of saline solution greatly reduces the mortality from collapse; the more often the patients survive collapse, the more important becomes the treatment of the subsequent uremia; with the present methods of treating uremia only about one-third of the cases recover.—*Philippine Journal of Science.*

LETTERS TO A NEUROLOGIST.

By JOSEPH COLLINS, M.D.,
NEW YORK.
PHYSICIAN TO THE NEW YORK NEUROLOGICAL INSTITUTE.

II.

New York, January 7, 1909.

My dear Doctor:—Somewhere I have read that an autobiography may be the more valuable in proportion to the amount of misrepresentation which it contains. If that is true, the contribution which I propose to make is of very little value. I want to give you some account of my life with the hope that you may be able to explain why it is that the light has gone out of it. I have no irresistible longing for confidential expansion; in writing to you I am moved chiefly by a sense of duty to myself. I feel also that confession is good for the soul, and I have heard or read that we get from others, if we are able to accept and to assimilate it, something which we never obtain by our own efforts. I recall once going to hear a popular, rather unconventional clergyman, and being struck by the yearning, expectant look in the faces of many of the congregation—"The desire of the moth for the star." Perhaps they were not ready for the message, perhaps he did not have one to give, for I shall not forget the portrayal of blankness on many of those faces when the sermon was over.

Your profession may have no message for me, or if it has, I may not be capable of interpreting it. I don't know just how to begin to tell you about myself. I have a morbid appetite for happiness, and the world has become to me a scene of misery. I married at eighteen a young man a few years my senior and of somewhat better social position; at least, his family had been wealthy for several generations, while mine were in straitened circumstances. I first met him at a little dance given by one of my schoolmates in the Christmas holidays of my last year at school. I was a very pretty girl and was considered unusually bright by my schoolmates. I was very much interested in music, in poetry, in art, in philosophy, and particularly fond of the mystic philosophers. To be perfectly frank with you, I think my interest in these things was superficial. Perhaps I thought them rather decorative, like an attractive environment, and felt that they gave me a mysterious charm. No doubt, in those days I took myself rather seriously. When, in addition to these attractions, I added that of being engaged to one of the best "partis" in our set, my head, in the eyes of my companions, was encircled with a romantic halo. I fancy adulation and admiration have been necessary to me from my earliest years. I married before I was 19 years old, and our son was born before I was 20. He is now 23, and my 43d birthday is not far off.

In the second year of our marriage, I plunged deeply into the whirl of social life. The novelty of it was more entrancing because of my simple bringing up. I was flattered and admired, and I enjoyed myself from morning until night. My husband apparently was always glad and ready to share my social engagements and pleasures, but in reality he is what is called domestic. He has never seriously tried to keep me from doing anything I have really wished to do, and fortunately he is not jealous. Also I must say he has never had cause to be. Although fond of admiration, the idea of a "grande passion" never appealed to me; it is not so much

that it would offend my morals as my sense of the fitness of things. A certain gleam in the eyes of a wood-be lover gives me a feeling of nausea, and I am quite sure that if I gave a man any rights over me it would not be long before I hated the sight of him.

My husband, in whom the paternal instinct, it seems to me, is abnormally developed, has wished for more children. At first I kept putting off the evil day until I should have more time or more inclination for the trial and trouble. The truth of the matter is that with the birth of my son I missed that growth of the soul which Balzac wrote about so convincingly and so charmingly. It must have been that I was too young to have borne a child or had not been properly appraised of the dignity and sacredness of the obligation. Possibly immaturity explains my conduct. I remember once when my boy was dangerously ill that I worked myself up into a sort of frenzy of anxiety. In the midst of it I caught sight of myself in the mirror, saw how grotesque my grief had made me look and instantly set about repairing the damage. Would I have done this if I had really loved him?

My son went to a preparatory school when he was ten years old, then to a finishing school, and finally to college, so that I scarcely had a chance to become intimate with him, and now, when I begin to feel a pride in his worth and attainments—for everyone thinks him clever and able—he is about to marry a girl whom I scarcely know, and I am afraid I will count for little in his life or in hers. Meanwhile, in spite of his essential goodness, I am beginning to find my husband's society excessively distasteful, and the commonplaces of domestic life, the visits to and from the family, the little round of duties, monotonous recurrence of meals, are insupportable. Indeed, the vapidness of my life at home gets more and more on my nerves every day. The truth is, my husband's point of view is not harmonious with mine. What he talks about fails to appeal to me; all his aims and ambitions seem so petty—I had almost said sordid. When I am nervous and sensitive to discordant sounds, do you wonder that when he comes clumsily or noisily into the room and sings, or whistles or yawns, I feel as if I should scream? In addition, I am not well, I have aches and pains all over my body. I often wake at dawn and fail to sleep again, and I am unable to digest my food.

For many years I had a new fad every winter, clog-dancing, playing the zither, private theatricals, tableaux vivants, raising dogs, bridge, riding to hounds, modeling in clay, a class in Italian—anything and everything, but now I feel too tired, too ill to make the necessary effort.

Other interests also have long palled on me. My friends no longer interest me; they seem so self-centered, and their conversation bores me. It is also beginning to dawn upon me that my society is no longer so attractive to them. Formerly I was able, if you can understand what I mean, to get possession of people, to exert a magnetic attraction, and for a time they would see with my eyes and hear with my ears, but this ascendency did not last very long. It was obviously a part of my vitality. I wonder if you will understand me when I say I lived always in a state of expectancy that someone would come upon the scene more attractive than the chosen devotee of the moment, or that something would turn up more exciting than anything I had yet experienced. My husband often says to me, "What is it you want that you have not got—a luxurious home in winter, a veritable summer palace, motors, horses, trained servants, all the money you care to spend, every wish gratified? Why are you discontented, unhappy, ill?" Why, indeed?

People still appeal to me, but they do not enthrall me, and secretly I have a contempt for them in their readiness to bow the knee to convention and tradition. I am sure that the atmosphere in which I live is unfavorable to the development of my soul; in truth, I have the greatest difficulty in finding anyone who shares my inclination for the esoteric and the symbolic, and I hunger for the society of one to whom symbolism in religion, art, and life means what it does to me. If I could meet a person like Walter Pater I feel that I should be understood, and that the spiritual communion which would exist between us would entail happiness. Formerly, I was very fond of music, but it no longer enthralls me, nor can I get exultation when I see beautiful pictures, as I could formerly. I have no desire to travel. Having spent much time abroad, the pleasures of fashionable resorts have palled upon me. Saddest of all, my looking-glass tells me that I am beginning to fade; the corners of my mouth droop, and even I can see that my expression is peevish and discontented. My rest at night is so much broken that I awaken in the morning unrefreshed in mind and body, weighted with the leaden anticipation of another day.

I think that my present condition is due rather to misfortune than to any great lack in my own nature. In the past, before this state of worry and helplessness set in, I often felt exalted impulses toward the good and the beautiful. It is true that religion as generally understood has made no appeal to me; but a beautiful sunset, a strain of music, a couplet of poetry would make me at peace with all the world. How often at such times have I felt that it would be entirely possible to relinquish my luxurious life and devote myself to the performance of some noble duty, such as caring for the sick and poor and the unfortunate. Many times have I planned to do so. It must be that my husband has not given me encouragement; that my spiritual growth has been stultified by his limitations and his altruistic Lilliputianism. I am sure that if he had cooperated with me to develop the finer parts of my character, that I should not now be left "naked to my enemies," to borrow Woolsey's famous line.

I wish it were possible for me to become a Roman Catholic. The warmth of their ceremonial attracts me; and their cathedrals, their services appeal to the symbolism of my soul. I sometimes think that if I were to join that Church it might awaken dormant sentiments and satisfy my heart and mind, which are so inadequately nourished.

For the past two or three years I have grown increasingly nervous and irritable, and I have had much advice and treatment from doctors. Now I am being urged to consult a Russian hypnotist in Paris. Perhaps you have heard that he accompanied Mrs. ——— when she returned to this country last year. He is the same man, I think, who has been over here to treat Mrs. ——— for headache. My husband thinks that I should go back to Aix, as the doctor there said that it was absolutely necessary for me to go back every year for five years before the treatment which he gave me would cure me, but Aix bores me to death, and the sight of

King George annoys me nearly as much as my husband. The truth is that no one pleases me; it all seems so empty and dreary. My life is not over at forty-three, is it? If it is not, it is rapidly becoming an unsupportable burden. Is nervous prostration staring me in the face, or am I threatened with insanity?

I must tell you that recently I have often thought I was going mad. I have been unable to control my thoughts; I have felt a sensation of hopelessness and insecurity which no one can understand who has not experienced the feeling of being utterly anchorless, bereft of what I suppose you call will power.

If you can give me any encouragement, or if you can show me the way out of this wilderness, you will earn my everlasting gratitude.

New York, June 1, 1908.

"Travaillons sans raisonner, c'est le seul moyen de rendre la vie supportable."—Voltaire.

My dear Madam:—You mistake ennui for disease. You are in search of happiness, not health. In fact, your quest is the same now as it has always been, only now that you have come to a time of life when the outside world is beginning to lose interest in you and when your vitality is not quite so dominant as it was, you say "cui bonum?", the question that is as old as mankind, and the answer to which depends entirely upon yourself. Certain ancient philosophers taught that the great secret of life consisted in placing our happiness in things which depend upon ourselves and not upon things which are at the mercy of circumstance. If I may judge from your letter, you certainly have not followed the teachings of such philosophers. Your life has been one of self-indulgence and lack of discipline. The only canon to which you have conformed your conduct is, "Do I want it?" You never asked, "What will the possession of this bring me? How shall I profit from this? How will others profit?" You have not known and you have not sought to learn if the gratification of your desires and the affirmation of your requests involved sacrifice upon the part of your husband or of your family.

You apparently believed that happiness was to be found by increasing your wants and by endeavoring to satisfy them, whereas in reality happiness is found by restricting one's wants. The great thing is to learn early the secret of renunciation. To get personally as much satisfaction as possible out of life and so to direct our conduct and activities that it will also be easier and surer for others to get it, this should be one of the chief objects of our existence. We should seek happiness in active life devoted to some absorbing condition, or in endeavoring to develop those emotions or intellectual tastes which are the fruit of the proper cultivation of our capacities, our endowments, and our fancies. But what have you done? You have rushed without ceasing, and now you are at a loss to understand why you are weary of the life that you have led, and fearful of the prospect that confronts you.

Have you ever seriously asked yourself the object and aim of life, not as an academic inquiry or as a contribution to the literature of immortality, but as an average woman, without particular training in religion or philosophy, might ask herself? If you have, you have probably reached the conclusion arrived at by the majority of us, that the object and aim of life is happiness. That, in reality, is what you are in search of now.

The relationship between the disease of our era, ennui, and dissatisfaction with life, or unhappiness, is not hard to find. It has been said that strenuousness is our national characteristic, but the disease has been mistaken for the remedial measure. We appear strenuous, but it is only our great effort to escape boredom. We are fearful lest we should have a few minutes or hours during which we may be obliged to think, or indulge in revery. We flee from abstraction as we flee from the plague. We in this country are so new at the game of life as it exists, and we are so hampered by the bonds of convention that we cannot play it from the point of view of the Hedonist. It bores us to live in the country. It bores us to dine at home. It bores us to restrict ourselves to our family circle. Reading for pleasure scarcely exists. Conversation as an art has perished as completely as the art of the Etruscans, and for table talk we must turn to Coleridge, Sidney Smith, or Emerson. Such a scene as that depicted recently by Dickinson in "A Modern Symposium" would be no more possible in this country than a discussion of Phædo at a fashionable dinner-party.

You see, I am endeavoring to point out to you that you are not entirely to blame for the state of desolation in which you find yourself. You cannot be absolved wholly, however, for I think much of your unhappiness can be traced to your voluntary and deliberate act of omission in failing to map your life during those twenty years of your early maturity when the constructive capacity is at its height, and in not, at the present time, cultivating those dispositions and tendencies which contribute to happiness. "Viellir est plus difficile que mourir, par la raison que renoncer une fois et en bloc à un bien coute moins que d'en renouveler le sacrifice tous les jours et en detail," saith Amiel.

It is at your age that, in nearly every country save ours, woman reaches the maturity of her charm and the height of her attractiveness. A sympathetic comprehension of persons and of life may give her an experience from which radiates that indefinite something that entrances and enthralls. Instead of being conscious of this power, you are overwhelmed with your helplessness and have no gratitude for the past, no hope for the future.

Can you not look back on your life and see why it is that you have failed to develop that equanimity and peace of mind which constitute the philosophy of late maturity? If you do so, you will find that you have sought happiness from without, rather than from within, and that such search is bound to be futile, sage and bard have testified from time immemorial—

"Thy body at its best,
How far can that project
Thy soul on its lone way?"

There are certain physical conditions which are essential to happiness, and of these that which we call health, or an approximation to health, is the most important. Nearly everyone, I presume, has known someone, usually a woman, who, despite semi-invalidism, has been self-sacrificing, courageous, resigned, cheerful, and magnanimous, a radiator of joy and goodwill, and who found ill-health quite consistent with happiness.

History abounds with examples, such as Symonds and Stevenson, showing that a capacity to receive,

to interpret, and to give pleasure, therefore to be happy, is not at all inconsistent with ill-health. In your own case, judging from the account that you have given me, it would appear that you have had exceptionally good health, nor can you legitimately accuse the rubicon that you now seek to bridge, rather than face its stream, with having anything material to do with your present state of mind. Just in proportion as the principles governing the causation of disease are discovered, and deductions drawn therefrom are established, so has the second great physiological epoch in woman's life, as an adequate exciting cause of disease of any kind, been relegated to the background. Not very long ago it was taught that nervous and mental disorders of various kinds were particularly liable to occur at this period of involution. Even to-day this belief is widespread among the intelligent laity, and such teaching is handed down from generation to generation in much the same way as was the poetry and legend of ancient Greece. In reality, aside from slight disturbances of the most conspicuous functions of the sympathetic nervous system, this period is often one of physical tranquillity, emotional growth, and intellectual maturation.

I cannot presume to advise you how you shall proceed to find your way out of the thicket into which the pursuit of pleasure has led you. No one can help you but yourself. The way out for you may be indicated; you may be aided to recall truths which no doubt are also platitudes, but the only one who can do anything with your character as it is now formed is yourself. First, you must battle with selfishness, for I fear that, insidiously and unconsciously, it has taken possession of you. What have you ever done for your family, for the community in which you live, for society, aside from an occasional "giving in" to your husband, or such sacrificial offering as a fancy dress ball, a musicale, or the gift of a check to Salvation Army, rescue mission, or hospital? I venture to say that you have never experienced a thrill from such conduct. Such delightful possession might have been yours had you ever done a truly unselfish act. To bestow something which costs us nothing may benefit the recipient, but not the donor.

"Who gives himself with alms feeds three,
Himself, the wandering poor, and Me."

Have you ever taken any real trouble about your charities? Have you sought out, at the cost of time and labor, any poor family to whom you could be an administering angel? Have you come to the rescue of the ignorant and erring of your own sex in their hour of direst need? Have you consoled them in their time of trial, and later on, have you by your unselfish sympathy encouraged them to face the world again? Have you ever proved yourself a true helpmate to your husband in any crises of his business life, and won his gratitude by your loyalty and devotion? Consider how much work there is in this world ready and waiting to be done!

Have you ever taken an interest in any of the questions of the day? There are many crying needs to be adjusted. You might devote some of your time, and all of your energy, to the establishment of a hospital for the treatment of the demi-poor, ill with so-called "functional" nervous diseases and the curable mental diseases. America well deserves the opprobrium of being the one great nation which makes no provision for those unfortunates who are not apparently sick and who are therefore excluded from all hospitals, but who in reality suffer infinitely more than those who have bodily ills. Such cases call for a much more elaborate and intricate therapy than typhoid fever, pneumonia, or broken bones.

Had you the slightest wish to protest against the enactment of a law to prevent humane vivisection when it was read before the Legislative Committee last year in Albany? You know, I have no doubt, that such diseases as diphtheria, hydrophobia, meningitis, and others have been stripped of their malignity, and that those terribly deforming and often fatal diseases, pulsating goiter and myxedema, now yield to treatment. And if you know this you know also that this epochal advance in therapy is entirely the outcome of experimentation upon animals. Many kindly but misguided people would stop this by the enactment of laws which forbid such experimentation. The very fact that a person of your social position had intelligence and interest enough to point out that we could not very well applaud field sports, in which animals are killed and maimed for amusement, and at the same time make laws which, put into action, would prevent investigations that save the lives of our children, would, I have no doubt, have had weight with the committee that had this matter in hand.

Do you realize that the problem of child labor in the cities of this country, and especially in the large cities, is one that urgently awaits solution? Do you know that earnest men and women, imbued with a spirit of eagerness to discharge their duty to their Creator and to their environment, are bending every effort to solve this problem, and solve it in such a way that it will not conflict with the principles of economics or of freedom?

Did you by chance see in a Sunday newspaper of recent date the account which one of our most talented operatic singers gave of her early life, and how generously and wholly she gave the credit for the success that had come to her to a kindly woman who not only provided her with the means necessary for the cultivation of her talent, but who encouraged her in the times of her despair and cheered her in the hours of her depression? The satisfaction that that woman must have in knowing that she has enormously contributed to the pleasure of thousands of people, and will continue to contribute, must be very great indeed.

But why enumerate? The more one does, the more one finds to do, and unselfishness is as capable of cultivation as any other quality. Indeed, it is not necessary to recall good deeds or to do good deeds in order to have the sense of happiness or to deserve the "well done, good and faithful servant." On the contrary, it is quite as possible to have it from thought as from act, but not the thought of introspection, of self-analysis of the good and evil of life. Indeed, it does not follow the thought of self at all, but of others, living and dead, and of the joy of life of those with whom we come in contact, and of the reputation and achievements of those who have gone before!

You may say that such counsel as I have to offer might have been of assistance had you received it twenty years ago, and you may think that the plastic stage of your life having passed, it is too late for you to avail yourself of it, but I think otherwise. One can do more with one's character at any age than with one's intellect. Read

the life of Alfieri, the Italian poet, and see what he did with his character and with his intellect at various ages. You will be astonished and benefited. Indeed, I am not at all sure that you are not more prepared now for the message which I have for you than you were when you were younger, particularly because happiness and contentment and peace of mind mean something different to you now than ten or twenty years ago.

While we are young, we are continually looking forward to something that will make us supremely happy—"Man never is but always to be blest." Youth is ever impatient for to-morrow, for next summer, for next year. The boy wants to be thought a man and the girl wants to look older. An undefinable something that is pleasurable waits the advent of next year, but when next year comes, anticipation is again projected beyond the moment. The truth is, we may be content, peaceful, pleasantly occupied, but we are never actively happy for more than a moment at a time. Nature is beneficent, the nearer we put ourselves in harmony with her laws, the more satisfaction we obtain. A well-spent youth means a happy old age. Youth is rarely a period of conscious happiness. We read great happiness into it across the valley of retrospection. As a matter of fact, when the stress and strain of life are over, when life's pleasures and responsibilities lessen, and we sit down to wait, unquestioning, we are quite as near to happiness as at any other time. The capacity to enjoy life is not peculiar to any age or either sex, it lies entirely in the individual. How often do we see those most apparently blessed by fortune, discontented, peevish, a prey to nervous disease, and on the other hand, the old, deformed and poor, at peace with themselves and with all the world, happy in putting to use the one talent.

For the sake of argument, let us agree that happiness does exist. Can we not also agree that it is almost independent of circumstances? As Heaven is surely a state and not a place, does not happiness exist solely in the spiritual side of our natures? Some favored mortals are blessed by having had a fairy godmother, who bestowed on them at their christening the greatest of all gifts, a good disposition, which is really, in a way, what is spoken of in the Bible as Charity. They do not have to struggle their lives through—young, they take all simple, natural pleasures naturally; old, they get pleasure from and live again in the young.

Humility and submission are qualities without which one cannot be at peace. At your age, the more important, for this time of life is full of renunciation—each day, each month, something is relinquished forever, but if one has cultivated the "seeing eye, the understanding heart," one is enabled to bear the inevitable with philosophy and gentle resignation. Taught by experience, one realizes that this world must be a training school for some unknown sphere, and that whether hereafter we continue to exist as individuals, or whether we only make, by passing through life, an eternal impression, it must all be worth while. There is no real waste in Nature; there must be some end and aim to this existence which our finite minds are unable to grasp.

On the side of your dressing mirror place a card inscribed with the sentence by Mme. da Deffaud:

"L'ennui est le tombeau de tous les sentiments."

Observations on Certain Forms of Infantile Anemia in Relation to the Hygiene of the School.—V. Giudiceandrea, from his experience in inspecting certain private and public schools in Rome, deduces certain conclusions with reference to the causation of some forms of anemia found in school children. Certain forms of anemia are not caused by the usual well-known morbid states, congenital and acquired, but seem to bear a relation to the conditions of the home and school life of the child. Between the ages of six and fourteen years there is a true scholar's anemia, which, in predisposed children, is brought about by the unhygienic conditions found in schools, especially the badly regulated bodily exercise and mental discipline. The anemia of growth, generally considered to be due to the growth in length of the body, without an equal growth of the hematopoietic powers, has much to do in causation with the hygiene of the family and of the school. The inspection of schools can be such as to assist in preventing these conditions, and the physician can be of great use, but his position in this matter is one of some delicacy.—*Il Policlinico.*

Galvanization of the Thyroid Gland and the Menstrual Function.—P. Galante says that there is a special relation between the diseases of the thyroid gland and the functions of the sexual organs. This is shown especially in exophthalmic goiter, in which the disease is accompanied by lack of sexual desire in the male and even impotence, and in the female by disturbances of menstruation. In the initial period of high tension there is metrorrhagia, while in the stage of cachexia amenorrhoea takes its place. The author details three cases of goiter observed by himself in which these relations were well shown. These cases demonstrate the necessity of early intervention in the treatment of exophthalmic goiter in order to obtain a cure. Galvanization of the thyroid gland has a marked influence on the menstrual function. The presence of pregnancy in this disease makes it necessary to use the greatest prudence in the use of this treatment, since abortion may be produced. In cases of dysmenorrhea accompanied by hyperthyroidismus, galvanization of the thyroid gives surprising results. The author believes that if this treatment be made use of in the acute psychoses which accompany Basedow's disease and disturbances of menstruation it will have an excellent effect.—*Annali di Elettricita Medica e Terapia Fisica.*

Mammary Opotherapy in Gynecology.—Batuaud describes a diminution of size of fibroid tumors of the uterus, especially of pure myomata, and a lessening of hemorrhages from the ingestion of the powdered substance of the mammary glands. Mammary opotherapy is indicated whenever we have too abundant menstruation, too short intervals between the catamenia, too prolonged periods, or hemorrhage between the regular periods. The medication brings back the normal rhythm of menstruation as to frequency, amount, and duration. It is useful in the menorrhagia of puberty, in young females with ovarian congestion causing metorrhagia, in salpongo-oophoritis with menorrhagia, and in metrorrhagia of fibroid tumors. It is also useful in hemorrhage of uterine sclerosis and other hemorrhages of the uterus at the menopause not allied with malignant growths. It is useless in hemorrhage from placental retention and from mucous or fibrous polypi. The dose is two powders of .50 grams per day, before meals. In hemorrhage between the periods there should be the same dose taken daily, and twice as much at the time of hemorrhage.—*Journal de Médicine de Paris.*

Appendicitis and Diseases of the Adnexa.—Paul Segond finds that appendicitis and diseases of the adnexa are frequently found together, and have a causative relation. The intimate relations of these two structures, their connection by a ligament, a chain of lymphatic, and the peritoneum and subperitoneal cellular tissue, all tend to account for the propagation of inflammatory lesions from one organ to the other. The two may be combined, the suppurative cavities being connected, or there may be only a surface lesion of one organ, while the disease of the other is fully developed. The diagnosis between an appendicitis and a right-sided inflammation of the adnexa is very difficult. When there are digestive disturbances in a salpingitis the appendix should be carefully examined. When a laparotomy is done for disease of the adnexa the appendix should be carefully sought for and if there is any suspicion of disease it should be removed. The indications for operation in all suppurative cases are imperative. When operation is to be undertaken in adnexal disease, if there is suspicion of appendicitis no vaginal operation should be done, and a median incision of the abdominal wall should be preferred.—*Gazette Médicale de Paris.*

New York, January 15, 1910.

THE ACTION OF MAGNESIUM AND CALCIUM ON THE ANIMAL BODY.

DURING the past few years a series of reports have emanated from the Rockefeller Institute, each describing some phase of the researches of Meltzer and others on the action of the salts of magnesium, calcium, and other bases upon the animal organism, each representing a link in a chain, which, when welded together, forms a distinctly valuable contribution to medical knowledge. This welding process has now been done by Meltzer in a paper presented at the Sixteenth International Medical Congress at Budapest, published in the *Deutsche medizinische Wochenschrift* for November 11, 1909, and abstracted in full in the MEDICAL RECORD, volume 76, page 1006.

The first fact of importance to be discovered by Meltzer was the remarkably powerful depressive action of magnesium when injected into rabbits, cats, and other animals. This was so extreme as to produce complete anesthesia and narcosis. Subcutaneous or intraspinal injections of magnesium sulphate or chloride were followed within fifteen to thirty minutes by a complete flaccid paralysis, and total loss of the sense of pain, to such a degree that even major operations could be performed with no sign of suffering on the part of the animal, the anesthesia lasting, as a rule, in the neighborhood of two hours and terminating in perfect recovery with but few after effects. This discovery led to the use of magnesium sulphate, especially by means of intraspinal injections of 25 per cent. solutions of the salt, for the production of anesthesia in operations upon the human body, and also in the treatment of tetanus. The results in the latter were striking, indeed. Within a few minutes after the first injection the convulsions and rigidity disappeared and the patients remained for hours or days in a state of rest, often resulting in complete recovery from the disease.

The general use of the drug, however, as an anesthetic, was prevented by the narrow margin of safety in its use, even comparatively slight increases in the dose administered causing, in the animal experiments, death from respiratory paralysis. A search for an agent antagonistic to the action of the magnesium, and protective against its dangers, was therefore instituted, and in 1908 an article was published by Meltzer and Auer showing the power of the salts of calcium to neutralize and overcome the action of magnesium. The demonstration of this was impressive. If an animal were given a large lethal dose of magnesium sulphate, and the experimenter waited until paralysis was complete, the reflexes lost, respiration stopped, and the heart action a mere flutter, and then injected intravenously a few cubic centimeters of calcium chloride or acetate, the effect was immediate. The respiration returned and deepened, the lid reflexes were renewed, and within one to two minutes the animal sat up and hopped away. In the authors' own words "intravenous infusion of various calcium salts is capable of completely reversing the pronounced inhibitory effect brought on by the various magnesium salts. The respiratory paralysis, the lost lid reflexes, the motor paralysis, the lost general reflexes, the general anesthesia, the loss of consciousness, the cardio-inhibitory depression, the lowering of blood pressure—are all reversed and restored in a very short time and by a comparatively small quantity of calcium. We do not know of any instance in biology of such a striking, we may say miraculous, antagonistic effect." This antagonistic action of calcium to magnesium occurred whenever the latter was administered subcutaneously, intramuscularly, or intravenously, but failed entirely if the primary injection was made into the medulla or the arachnoid spaces. Further researches by Meltzer and Joseph demonstrated that the administration of physostigmine in therapeutic doses, while in no way interfering with the anesthetic effect of magnesium, decidedly aided in preventing the respiratory paralysis.

In concluding his Budapest paper Meltzer calls attention to the fact that of the four elements, magnesium, calcium, potassium, and sodium, the first is the most poisonous to the animal organism, and the toxicity decreases in the order named. The relative toxicity of the ions of these bases is in inverse proportion to the amount normally found in the serum of the animal, or, in other words, the less accustomed a tissue is normally to a substance, the more poisonous that substance is for the particular tissue.

These researches of Meltzer and his associates have developed a mass of knowledge not only new, but striking in its import and possibilities. As yet their practical application to the treatment of disease may not be very apparent, but whether or not they will ever lead to the adoption of a safe general anesthetic, administered by subcutaneous injection, from the viewpoint of the physiologist and the pharmacologist their value is considerable.

NASAL DIPHTHERIA.

PROPHETS of ill are not wanting who assert that the winter which is now upon us will show rather more than the usual number of cases of infectious disease, especially of diseases involving primarily the upper respiratory tract. If that is so, speaking for one of the worst and formerly most fatal of these among children of tender years, one will do well to remem-

ber that the Klebs-Loeffler bacillus is ever present among us, and that its tenacity and virulence vary considerably in different years. We are prone ever to think of diphtheria as a pharyngeal and laryngeal condition, and, fortunately, we have learned to regard every case of sore throat in children with suspicion. Experience has taught that many lives have been needlessly sacrificed because we have been too trusting of our diagnostic prowess, and, hence, every case of sore throat with exudate is now submitted to microscopic test by all careful practitioners. It is rather curious what surprising reports one may receive from a focus that looks like acute follicular tonsillitis or mycosis, or a result of some disorder of the stomach; consequently, when called to see a child, no matter what the alleged cause of the illness, one ought always carefully to inspect the mouth. This means thorough and systematic examination of the inner surface of the cheeks, gums, roof of mouth, tonsils, pillars of fauces, oropharynx, and the area beneath the tongue. Such care followed by immediate taking of smears and cultures will ofttimes well repay one the slight trouble which is thus occasioned.

We should not, however, attend too assiduously to the mouth and throat at the expense of overlooking an important nasal condition. Frequently the mother neglects to mention to the physician that the child has had a foul discharge from the nose for several days or weeks, thinking that what is considered to be an ordinary cold will shortly clear up without treatment. It is just these cases that furnish the greatest number of diphtheria carriers; for after the acute symptoms of fever, vomiting, anorexia, etc., have passed, the child is up and about, playing more or less half-heartedly, yet not really sick as the mother understands the term. Nevertheless, many such children harbor the Klebs-Loeffler bacillus in nearly pure culture, and it is probably because of the antiseptic properties of the nasal secretion that general toxic symptoms are not more in evidence.

The nasal discharge is greenish or greenish yellow, is very irritating, causing excoriation of the skin of the nose and lip, and is accompanied by slight bleeding and crust formation. Occasionally large pieces of membrane forming a partial cast or mould of the nasal fossa will be discharged. It is not unlikely that many cases of chronic nasal discharge which continue into youth as an atrophic rhinitis find their origin in a Klebs-Loeffler infection which becomes so attenuated as finally to lose its distinctive morphology. When a diagnosis of nasal diphtheria is made in an adult, an injection of not less than 5000 units of antitoxin should be at once administered—the rules for children have already been fairly well described by many authors. The nose should be irrigated with physiological saline solution every two hours, followed by a spray of lactic acid bacillus. Just what rôle the latter plays is not yet scientifically proven, but the tendency is to ascribe a sort of selective affinity on the part of these warring bacilli for each other. There is no question that this is sometimes a very helpful measure. Text-book descriptions of nasal diphtheria are for the most part brief and unsatisfactory, but the importance of early recognition of this condition needs to be emphasized.

CROTALIN AS A THERAPEUTIC AGENT.

Snake-venom, like all poisons, may be employed as a remedy for certain affections. Thomas J. Mays of Philadelphia has for some time been investigating the matter. His experimental study of crotalin (rattlesnake venom) led him to believe that the substance affects profoundly the cerebrospinal nervous system, and especially that part of the spinal cord which comprises the respiratory center and other closely allied centers (*American Journal of Clinical Medicine*, December, 1909). A. J. Wall, perhaps, has made the most elaborate experiment in regard to snake venom under the auspices of the British Government in India, a fertile field for work in this direction. He and other investigators demonstrate that the powerful snake venoms all actively affect the structures of the upper part of the spinal cord which are included in the medulla oblongata. According to the same authority cobra venom in man exercises a similar effect, only intensified, to that exerted by crotalin. The dried venom of the rattlesnake, known as crotalin, has a neutral reaction, is soluble in water and glycerin, and possesses all the physiological properties of the fluid secretion. Armstrong states that it has the following percentage composition: Carbon, 45.76; nitrogen, 14.30; hydrogen, 6.60; sulphur, 2.50. Mays concludes that 1-100 grain may be considered the average dose, to be repeated once a week. It can be given hypodermically, and by mouth in fluid form, as a reinforcing administration. The local effects are painful for a short time, and edematous swellings occur.

The author gives his experience with the therapeutic action of crotalin in several diseases. In cases of phthisis he has had most favorable results from the employment of the remedy, and it was noted especially that crotalin had a marked influence on many of the physical signs of phthisis and other lung diseases, notably on the auscultatory signs. Acute pneumonia, asthma, hay fever, and spasmodic cough have been greatly benefited by the employment of crotalin. Neuralgia, sciatica, brachialgia, and lumbago have disappeared completely and rapidly, according to Mays, under treatment with crotalin. And, lastly, epilepsy and multiple sclerosis have yielded to a great extent to this form of treatment, but in the case of these diseases experience has been too limited to pass a definite opinion. Mays concludes that there is a great future for the employment of crotalin in medicine, and hopes that it may be fully tested by the profession. All experiments with deadly snake venoms prove that the poison has a special affinity for the respiratory center and those ganglia allied to it in the medulla oblongata which are in connection with the vagus, and it may be well, therefore, indicated in certain respiratory diseases and those affecting some of the nerves in connection with the respiratory center.

The Effect of Alcohol Upon Gastric Secretion.

That the habitual use of alcohol in excess exercises a very injurious effect upon the functions of the stomach is sufficiently well known. Yet there have been surprisingly few attempts to study its influence by the only exact method available, that is, by the administration of test meals and the examination of the gastric juice obtained after them. Nellis B. Foster alone has carefully examined a number of patients in this respect and has found that a great majority of them secrete more than the normal amount of mucus, while the free hydrochloric acid in their gastric juice is diminished below the average values. In the *Zeitschrift für physikalische und diätetische Therapie* for December, 1909, Eisenhardt reports a careful study of the matter in the case of thirty patients, all of whom gave a reliable history of chronic misuse of alcohol in the form of beer and other spirituous beverages. Twenty-two of the thirty suffered from the subjective symptoms that usually accompany alcoholic gastritis, while eight others had no complaint whatever, though chemical examination of their gastric juice showed marked deviations from the normal. Three patients had gastritis accompanied by an excess of acid in the gastric juice, three others showed low acid values, while the majority, or twenty-three of the remaining twenty-four, showed the presence of "anacid gastritis" of the type that is usually associated with chronic alcoholism. The motor functions of the stomach were for the most part exaggerated, so much so, indeed, that Eisenhardt was compelled to express the contents of the stomach fifty minutes instead of the usual one hour after test meals were given. The functions of the intestines appeared to be much less affected, a result which is well explained by the fact that a part of the alcohol is absorbed from the stomach and the portion that reaches the intestines is much diluted and is distributed over a greater surface than when it first reaches the stomach. All of the results obtained were controlled by repeated examinations so that accidental findings were excluded. These results seem to corroborate the usual teachings in the matter; they add to them, however, the weight of experimental evidence and not that of mere conjecture founded upon subjective symptoms.

The Standardization of Drugs.

A bill has been introduced into Congress by Representative Coudry of St. Louis, providing for a single national standard of purity and strength for all drugs used in the treatment of disease in man or animals. The bill, as published in *The Pharmaceutical Era* of December 23, is rather crude and badly constructed, and if passed in its present form would probably give work to the courts for its interpretation, but in principle it is excellent and urgently needed. Under the provisions of the pure food law the U. S. Pharmacopeia and the National Formulary are the legal standards for all the drugs listed therein. But there are objections to such a provision, for neither of these books is a government publication, the standards they set up may be changed from time to time, and indeed have frequently been changed, without any apparent reason, and moreover there are many drugs prescribed daily by physicians which are not in the Pharmacopeia. The only permanent body claiming authority in the matter of the standardization of non-official drugs is one the authority of which is not recognized by the majority of the medical profession of the country. A bill written in intelligible and unequivocal language, entrusting the task of the standardization of all drugs, within and without the Pharmacopeia, to the Marine Hospital Service or some government-appointed commission of experts, would doubtless receive the warm support of the physicians and pharmacists of the country.

Reduction of Membership Dues by the American Medical Association.

We learn from an announcement in the *Journal of the American Medical Association* that the dues for membership in the Association have been reduced from five dollars to one dollar per annum. The announcement reads: "The annual assessment for membership shall be one dollar; and the price of subscription to *The Journal* shall be four dollars for members." There has been much complaint by members that they have received no benefit from the enormous financial success of the Association, and they will be pleased to learn that the officials have at last decided to let them share in the prosperity of their organization. The new rule will also no doubt result in a large increase in membership, for with the reduction of dues to one dollar many who do not care to subscribe to the official journal and who have hitherto held aloof because of the heavy assessment, may now be induced to join the society.

News of the Week.

The Harvey Society Lecture.—The fifth lecture of the Harvey Society will be delivered by Prof. Ludwig Hektoen of the University of Chicago, on Saturday evening, January 15, 1910, at 8:30, at the New York Academy of Medicine, 17 West Forty-third street. Subject: "On Certain Phases of the Formation of Antibodies."

The Tuberculosis Crusade of 1909.—Based on reports gathered from all parts of the United States, the National Association for the Study and Prevention of Tuberculosis has issued a bulletin in which it is stated that $8,180,621.50 was expended during the year just closed by the various interests fighting consumption in the United States. The bulletin, which is preliminary to a longer report, shows that in the year 1909 over 10,000,000 pieces of literature were distributed, and that 117,312 patients were treated and assisted by the sanatoria, dispensaries, and antituberculosis associations. By far the largest amount of money spent during the past year was for the treatment of tuberculous patients in sanatoria and hospitals, $5,292,289.77 being expended in this way. The antituberculosis associations spent $975,889.56, the tuberculosis dispensaries and clinics, $640,474.64, and the various municipalities, for special tuberculosis work, spent $1,111,967.53. The antituberculosis associations distributed the most literature, spreading far and wide 8,400,000 copies of circulars, pamphlets, and other printed matter for the purpose of educating the public about consumption. The health departments of the different cities also distributed more than 1,056,000 copies, which, with the work done by State departments of health, brings the number of pieces distributed during the year well

over 10,000,000. The largest number of patients treated during the year was by the dispensaries, where 61,586 patients were given free treatment and advice. The sanatoria and hospitals treated 38,758 patients, while antituberculosis associations assisted 16,968. New York State leads in the antituberculosis work done during the past year, having spent more money, distributed more literature, and treated more patients than any other State. Pennsylvania comes next and Massachusetts is third. The next seven States are Illinois, Maryland, New Jersey, California, Colorado, Connecticut, and Ohio.

Preventorium to Leave Lakewood.—In a letter addressed to Governor Fort of New Jersey, recently, the president of the Children's Tuberculosis "Preventorium," at Lakewood, stated that, owing to the opposition aroused against the project, the trustees had voted to move the institution from Lakewood.

Health Commissioner of New York City.—Mayor Gaynor has announced the appointment of Dr. Ernst J. Lederle as Health Commissioner to succeed Dr. Darlington. Dr. Lederle was Health Commissioner during the term of Mayor Low.

Mortality Rates in American Cities.—The Bulletin of the Chicago Health Department states that from the latest available returns of the fourteen largest American cities for the year 1909, death rates, computed on figures of population supplied by the United States Census Office, are as follows: Cleveland, 13.2; Chicago, 14.0; Milwaukee, 14.6; Detroit, 14.8; Pittsburg, 14.8; Buffalo, 15.1; St. Louis, 15.5; Philadelphia, 16.3; New York, 16.6; Cincinnati, 16.8; Boston, 17.6; Baltimore, 18.1; Washington, 18.5; New Orleans, 20.6. It is interesting to note that of the six healthiest large cities in the United States, five are located on the Great Lakes. From typhoid fever—the disease by which many authorities still gauge the sanitary status of a community—Chicago has, for the first time in its history, a lower death rate than any of the fourteen largest American cities. In each 100,000 inhabitants Chicago had 12.1 deaths from typhoid; Cleveland had 12.4; Cincinnati, 12.5; New York, 12.7; St. Louis, 14.4; Boston, 14.6; Buffalo, 18.9; Philadelphia, 22.2; Milwaukee, 23.3; Pittsburg, 24.0; Detroit, 25.5; New Orleans, 29.0; Baltimore, 31.2; Washington, 37.0.

Dr. Edward L. Munson, Major-Surgeon United States Army, has just been awarded the Seaman Prize of the Military Service Institute for 1909, for the best essay on the question "Should medical officers be responsible for the health and sanitation of the troops with whom they serve; and, if so, what should be their powers and duties? The prize amounts to $100, and is offered by Dr. Louis L. Seaman of New York, late Surgeon United States Volunteers, whose interest in the promotion of the efficiency and status of the military medical service is well known in this country and abroad.

Health Legislation in Ohio.—Three bills relating to public health matters have been prepared by the Ohio State Board of Health for the next Legislature. One is a bill to authorize the State Board of Health to establish a bureau for the prevention of infectious and contagious diseases, and to appoint necessary district medical inspectors. The bill provides in brief for a division of the State into not to exceed twelve districts, and for the appointment of a properly qualified physician as medical inspector for each district. Such inspectors may be selected after an examination to determine the fitness of applicants. It is provided that "The State Board of Health shall respond promptly when called upon for assistance by any local board of health or health officer, or the mayor of any city or village, or the justice of the peace of any township, and shall send a medical inspector to aid in diagnosing an infectious or contagious disease, in discovering its cause or origin, or in the enforcement of measures for its prevention." A second bill has been prepared, "To authorize the State Board of Health to produce antitoxin for free distribution for the cure and prevention of diphtheria." Under the present law, county commissioners are authorized to pay for diphtheria antitoxin, but only for use in indigent cases. The other bill is entitled, "A bill to promote the health of school children and to protect them from the evils arising from undiscovered or uncared-for physical defects and from contagious and infectious diseases." It provides in brief that every school child shall annually be examined by its teacher, and tested for sight, hearing, and obstruction to breathing. This is to be done according to directions to be prescribed by the State Commissioner of Common Schools, after consultation with the State Board of Health.

Medical College in Richmond Burned.—The University College of Medicine in Richmond, Va., was destroyed by fire on January 6. The adjoining Virginia Hospital was saved only with great difficulty. The Richmond College has offered the use of its buildings to the institution until the wrecked building can be rebuilt.

The "Lancet-Clinic" Enlarged.—With the issue of the January 1 number of the *Lancet-Clinic* this journal enters upon its one hundred and third volume. The publication, which has appeared for so many years as a small magazine-sized pamphlet, now appears in a larger form, to correspond with the other weekly medical journals of this country. The editor emphasizes the fact that it is no longer a local journal, but that "its theater is the United States, with especial reference to the Mississippi Valley."

The Illinois State Board of Health has issued a circular entitled "The Cause and Prevention of Consumption." This is the eighth revised edition of this pamphlet. It contains sixty-eight pages of instruction and advice upon the subject.

A "Pedicure Clinic" to be Established.—An announcement has been made in New York of the organization of a new institution to be called the People's Pedicure Clinic, the purpose of which will be to give to the indigent poor free treatment by chiropodists in a manner similar to the medical clinics of the city. The institution is the first of its kind in New York, if not in the world. Dr. Joseph P. Salomon will be the chiropodist in charge.

Health Agent Sued by Farmer.—An action for damages is being brought against the Chief of the Bureau of Sanitary Inspection of the New York City Board of Health by a farmer and dairyman of Roxbury, N. Y. The cause of the suit is the action of the Board of Health, through its chief inspector, in forbidding a dairy to receive milk from the farm of the complainant on the ground that the barns were in an unsanitary condition. The suit is to be a test case.

A Vaccination Fraud.—A young man who said

that he was a medical student was arrested recently in Long Island City on the charge of impersonating an officer. He had been representing himself as an agent of the Board of Health, and on this authority had insisted in vaccinating a number of people, for which he collected fifty cents a head.

The Americal Hospital of Paris has recently received a donation of $25,000 from Mrs. William B. Leeds in memory of her late husband.

Hospital Destroyed.—A dispatch from Vienna describes an accident which occurred on January 8 at Raibi, in Carintia. The sudden subsidence of the site of a disused mine completely engulfed a small hospital building. Not a vestige of the hospital remained, and only a huge cavity in the ground was to be seen. Seven inmates of the hospital, including Surgeon Wesseley and his family, perished.

Williamsburg Medical Society.—At the stated meeting of the society, held December 13, 1909, the following were elected officers for the ensuing year: *President,* Dr. Joseph Merzbach; *Vice-Presidents,* Dr. S. R. Blatteis and Dr. Adolph Bonner; *Secretary,* Dr. Alexander Spingarn; *Treasurer,* Dr. M. I. Levitt.

College of Physicians of Philadelphia.—At a stated meeting held January 5 Dr. Joseph Sailer read a paper entitled "Chronic Appendicitis." Dr. S. Weir Mitchell presented on behalf of the widow of the late Professor Henry C. Chapman a portrait by Sully of the late Professor Nathaniel Chapman; also, on behalf of Hampton L. Carson, Esq., silhouettes of Dr. John Redman, Dr. Samuel Powel Griffith and Dr. Abraham Chovet; also, on behalf of Dr. Henry D. Jump, a gold watch at one time belonging to the late Dr. D. Hayes Agnew. The following officers were elected for the ensuing year: *President,* Dr. G. E. de Schweinitz; *Vice-President,* Dr. Wharton Sinkler; *Secretary,* Dr. Thomas R. Neilson; *Treasurer,* Dr. Richard H. Harte; *Honorary Librarian,* Dr. Frederick P. Henry.

The Indianapolis Medical Society.—At the annual election of officers held January 4, the following officers were chosen: *President,* Dr. Samuel E. Earp; *Vice-President,* Dr. J. L. Freeland; *Secretary and Treasurer,* Dr. Roscoe H. Ritter.

Camden City Medical Society.—At its annual meeting, held January 4, the following officers were elected for the ensuing year: *President,* Dr. William H. Pratt; *Vice-President,* Dr. J. W. Martindale; *Secretary,* Dr. W. I. Kelchner; *Treasurer,* Dr. Emma Richardson; *Librarian,* Dr. Joseph H. Wills; *Historian,* Dr. A. B. Davis.

The Blue Earth County (Minn.) Medical Society, at its annual meeting, held December 25, 1909, elected the following officers: *President,* Dr. E. W. Benham of Mankato; *Vice-President,* Dr. H. B. Grimes, Lake Crystal; *Treasurer,* Dr. Lydia Osborn of Mankato; *Secretary,* Dr. T. C. Kelly of Mankato; *Censor,* Dr. A. G. Liedloff of Mankato.

The Fort Madison County (Ia.) Medical Society, meeting on December 27, 1909, at Fort Madison, elected the following officers: *President,* Dr. E. C. Chapman; *Vice-President,* Dr. W. C. Kasten; *Secretary and Treasurer,* Dr. Austin Philpott.

The Kennebec County (Me.) Medical Society, at its annual meeting at Augusta, December 30, 1909, elected the following officers for the ensuing year: *President,* H. E. Milliken of Waterville; *Vice-President,* R. H. Stubbs of Augusta; *Secretary and Treasurer,* Wellington Johnson of Augusta; *Censor,* O. C. S. Davies of Augusta.

The Santa Cruz County (Cal.) Medical Society held its annual meeting at Santa Cruz on December 20, 1909. The officers elected were: *President,* Dr. S. T. Pope of Watsonville; *Vice-Presidents,* Dr. E. B. Philbrook of Santa Cruz, and Dr. F. H. Koepke, of Watsonville; *Secretary and Treasurer,* Dr. E. E. Porter of Watsonville; *Censors,* Dr. A. F. Davis of Soquel, Dr. S. C. Rodgers of Watsonville, and Dr. W. A. Phillips of Santa Cruz.

The Sharkey County (Miss.) Medical Society met at Anguilla December 23, 1909. The officers elected were: *President,* Dr. S. K. Barrier; *Vice-President,* Dr. S. T. Hamberlin; *Secretary and Treasurer,* Dr. L. E. Martin.

The Washtenaw County (Mich.) Medical Society, meeting at Ann Arbor, December 29, elected the following officers: *President,* Dr. James Breakley; *Vice-President,* Dr. Waldron; *Secretary-Treasurer,* Dr. Keating.

The Hopkins County (Tex.) Medical Society at a meeting at Sulphur Springs has elected the following officers for 1910: *President,* Dr. W. E. Connor; *Vice-President,* Dr. J. R. McCauley; *Secretary,* Dr. M. C. Sheppard; *Censors,* Drs. J. J. Dial, S. B. Longino, and W. A. Clark.

The Jackson County (Tenn.) Medical Society has elected the following officers: *President,* Dr. J. W. Boggess; *Vice-President,* Dr. W. C. Maples; *Secretary and Treasurer,* Dr. Edward Boyd; *Censor,* Dr. S. H. Jones.

The Lonoke County (Ark.) Medical Society has elected officers for 1910 as follows: *President,* Dr. S. A. Southal of Lonoke; *Vice-President,* Dr. C. D. Ware of England; *Secretary-Treasurer,* Dr. F. A. Corn of Lonoke; *Assistant,* Dr. S. S. Beatty of England.

The Madison County (Ala.) Medical Society at a meeting at Huntsville elected the following officers: *President,* Dr. Claud Pettus; *Vice-President,* Dr. M. R. Moorman; *Secretary and Treasurer,* Dr. Edgar Rand; *Censor,* Dr. W. C. Wheeler.

The Milwaukee County (Wis.) Medical Society has elected the following officers: *President,* Dr. L. F. Jermain; *Vice-President,* Dr. W. A. Batchelor; *Secretary,* Dr. Daniel Hopkinson; *Treasurer,* Dr. Joseph Kahn; *Censor,* Dr. A. W. Gray.

The Mitchell District (S. D.) Medical Society has elected officers for 1910 as follows: *President,* Dr. Bert Menser of Bridgewater; *Vice-President,* Dr. E. W. Jones of Mt. Vernon; *Secretary,* Dr. W. R. Ball of Mitchell, and *Treasurer,* Dr. B. A. Bobb of Mitchell.

The Monteray County (Cal.) Medical Society, at the meeting at Pacific Grove, Cal., elected the following officers: *President,* Dr. T. C. Edwards of Salinas; *Vice-President,* Dr. M. Ritchie of Pacific Grove; *Secretary,* Dr. H. T. Crabtree of Salinas; *Treasurer,* Dr. John Parker of Salinas; *Censor,* Dr. J. E. Fankin of Gonozales.

The Muskogee County (Okla.) Medical Society, meeting recently, elected officers as follows: *President,* Dr. H. C. Rogers; *Vice-President,* Dr. S. P. Watkins; *Secretary-Treasurer,* Dr. H. T. Ballentine.

The Bastrop County (Tex.) Medical Society, meeting at Bastrop recently, elected the following

officers for 1910: *President,* Dr. N. B. Harris; *Vice-President,* Dr. O. N. Mayo; *Secretary and Treasurer,* Dr. J. G. Jones.

The Christian County (Ky.) Medical Society, meeting at Hopkinsville, Ky., December 23, elected officers for the ensuing year as follows: *President,* Dr. B. A. Caudle; *Vice-President,* Dr. James A. Young; *Secretary,* Dr. J. H. Rice; *Censor,* Dr. T. W. Blakey.

The Jefferson County (Ala.) Medical Society held its annual meeting at Birmingham, December 21, and elected the following officers: *President,* Dr. George W. Brown of Pratt City; *Vice-President,* Dr. E. S. Casey; *Secretary and Treasurer,* Dr. Charles E. Dawman; *Censor,* Dr. T. D. Park.

The Memphis and Shelby County (Tenn.) Medical Association, at its annual meeting at Memphis on December 21, elected officers as follows: *President,* Dr. E. C. Blackburn; *Vice-President,* Dr. J. W. Price; *Secretary,* Dr. B. N. Dunavent.

Obituary Notes.—Dr. John J. Archinard of New Orleans died at his home December 27, 1909, aged 38 years. He was a graduate of the medical department of Tulane University in 1893. He served as surgeon-major of the Second Louisiana Volunteers during the Spanish-American War. Dr. Archinard had the chair of clinical microscopy in the post-graduate department of Tulane. He was an ex-president of the Orleans Parish Medical Society, a vice-president of the Louisiana State Medical society, and a member of the American Medical Association.

Dr. James A. Burroughs of Asheville, N. C., died at his home December 29, 1909, aged 53 years. He was a graduate of the Louisville Medical College in 1882. At the time of his death Dr. Burroughs was the president of the North Carolina Medical Society, and was considered one of the leading authorities on tuberculosis in the South.

Dr. J. L. Carson of Bakersfield, Cal., died at his home on December 24, 1909, aged 48 years. He was a graduate of the Northwestern Medical College of St. Joseph, Mo., in 1894, and was a member of the Kern County Medical Society, the Medical Societies of the State of California, and the American Medical Association.

Dr. Guy M. Dunning of Lansing, Mich., died at his home December 24, 1909, aged 40 years. He was a graduate of the University of Michigan in 1904, and was a member of the Ingham County Medical Society, the Michigan State Medical Society, and the American Medical Association.

Dr. Martin A. Gilreath of Selma, Cal., died recently at his home. He was a graduate of the Vanderbilt University in 1891, and was a member of the Fresno County Medical Society, and the Medical Society of the State of California.

Dr. Alfred H. Hoadley of Northampton, Mass., died at the Dickenson Hospital in that city December 29, 1909, as the result of blood poisoning, aged 54 years. He was a graduate of the Albany Medical College in 1886, and was a member of the Hampshire County Medical Society, the Massachusetts Medical Society, and the American Medical Association.

Dr. Charles N. Lake of Detroit, Mich., died at his home December 26, 1909. He was a graduate of the Harvard Medical School in 1895, and was a member of the Wayne County, and the Michigan State Medical Societies.

Dr. H. K. Man of Dalton, Ga., died in Atlanta, December 26, aged 65 years. He was a graduate of the Medical Department of the University of Nashville in 1871, and had practised for many years in Atlanta before moving to Dalton.

Dr. J. Frank Perry of Boston, Mass., died on December 31, 1909, at the Boston City Hospital, aged 64 years. Dr. Perry was a graduate of the Harvard Medical School in 1873. He was at one time the editor of the *Boston Journal of Health,* and later established the Blue Hills Sanatorium at Milton. He was a member of the Suffolk District and the Massachusetts Medical Societies.

Dr. John Skinner of Roxbury, Boston, died at his home December 27, 1909, aged 85 years. He was a graduate of the Harvard Medical School in 1856, and was a member of the Suffolk District Medical Society and the Massachusetts Medical Society.

Dr. George E. Woodbury of Methuen, Mass., died suddenly at his home on December 26, 1909, aged 71 years. He was a graduate of the Dartmouth Medical School, a veteran of the Civil War, and a member of the Essex District Medical Society and the Massachusetts Medical Society.

Dr. Allen S. Heath of New York City died recently, aged 89 years. He was the oldest living graduate of the Medical Department of New York University, having received his degree in 1844. Dr. Heath during the Civil War was a surgeon in the navy, and later chief surgeon of the staffs of General King in West Virginia and of General Corcoran in Georgia.

Dr. Alfred Matthias Spalding of New York died recently at Speonk, Long Island, aged 50 years. He was a graduate of the College of Physicians and Surgeons in New York in 1883, and was a member of the Academy of Medicine and the Medical Society of the State of New York.

Correspondence.

NONALCOHOLIC CIRRHOSIS OF THE LIVER.

To the Editor of the Medical Record:

Sir:—Dr. Benedict's interesting and instructive paper in your issue of December 25 on "The Frequency of Hepatic Sclerosis in Nonalcoholics" leads me to ask permission to occupy a small portion of your valuable columns in recording a case of extreme hepatic sclerosis in a single woman of forty, in which there was not the slightest possibility of an alcoholic causation.

The last and fatal illness of the patient in question was ushered in by a sudden and profuse hemorrhage from the stomach, which was mistaken for and treated as a gastric ulcer by her physicians. After six weeks the patient went out, for the first time, on a chilly spring day. This was quickly followed by an acute pleurisy and pericarditis, which resulted fatally. The autopsy revealed an extreme degree of hepatic cirrhosis (atrophic type), large varices at the lower end of the esophagus (the probable source of the gastrorrhagia), extensive plastic pleurisy, and a pericarditis, with thick buttery layers of lymph between the membranes.

This patient had never exhibited during life any of the ordinary signs of cirrhosis; at least, none that were recognized by her medical attendants, who were men of exceptional eminence as diagnosticians. The compensatory circulation had been apparently perfectly established. But the history was significant and important from an etiological standpoint. The patient, as already stated, had never, except on rare occasions, used alcohol, not even during menstruation, as is so often the custom with women. She had been a sufferer, however, for many years from a subacute arthritis of the smaller joints of the hands and feet, which was regarded by her physicians, because of strong gouty antecedents, as a manifestation of that disorder of metabolism. From her youth, also, the patient had been a

large consumer of highly seasoned foods, condiments, and pepper—particularly red pepper, of which she ate liberally at most of her meals. Whether this was to relieve the dyspeptic symptoms from which she suffered in the later years, or was the cause of the latter, cannot now be said. But as this partiality for condiments dated from early childhood it has always seemed to the writer that it was not only the probable cause of the gastrointestinal catarrh, but possibly, also, of the arthritis, from the absorption of toxins, which there is some evidence to show may stand in a causative relation to some forms of chronic arthritis. But this, although related to the subject of this letter, is not its main purpose, which is to put upon record a closely observed case of marked hepatic cirrhosis, wherein alcohol as an etiological factor can be positively ruled out, and in which indulgence in highly seasoned foods, associated with gastrointestinal disorder, was a prominent feature in the life history of the patient.

D. J. Milton Miller, M.D.
Atlantic City, N. J.

OUR LONDON LETTER.

(From Our Regular Correspondent.)

EVOLUTION OF THE BRAIN—DIVERGENT VIEWS OF ANGINA PECTORIS—ANOTHER MEDICAL RESEARCH ENDOWMENT—HOSPITAL SUNDAY FUND.

London, December 22, 1909.

Professor Elliot Smith, F.R.S., in the capacity of Arris and Gale lecturer at the Royal College of Surgeons, has just delivered a course on "Some Problems Relating to the Evolution of the Brain." The appropriateness of the college for a discussion of this subject is obvious from the fact that most of our knowledge about it has resulted from the work carried on in the Museum during the last seventy years. At first he dealt with the matter from the historical point of view. He described the great work of Sir Richard Owen on the structure of the brain in the marsupialia in 1836. Then came the destructive criticism of his successor in the conservatorship and the consequent retardation of the growth of a true knowledge of cerebral morphology. Owen's work underwent a temporary eclipse in the controversies occasioned by the publication of Darwin's "Origin of Species," the defenders of which displayed a degree of animosity against Owen that they failed to discriminate between good work and bad. But the overthrow of Owen's excellent work on the brain of the marsupialia was merely temporary. Discredited for a quarter of a century, it had been rehabilitated by recent research, and had become the foundation of our present knowledge of the morphology of the brain in the vertebrata.

In the second lecture Professor Smith dealt with the nature and origin of the neopallium, the disposition of the hippocampal formation, and the changes it undergoes in certain mammalia. He also attempted to explain some current misconceptions of the arrangement of the olfactory paths. He considered the state of the hemispheres in reptilia, amphibia, and dipnoi, and pointed out discrepancies in the views of several observers. Speaking of the early neopallium, he repudiated the term "archipallium," which had been wrongly attributed to him.

In the third lecture the professor indicated the nature of the factors engaged in preparing the way for the evolution of the neopallium, and the results of the operation of these factors in remodeling the architecture of the brain and indirectly of the whole nervous system, and even of the body which it subserves. He likened the nervous system of the lower vertebrata to a confederation of more or less autonomous states. The cerebrum chiefly belonged to the sense of smell and perhaps also to that of taste, but contributed its share to the control of the commonwealth and was itself only slightly influenced by the other sensory mechanisms. Impressions of sight were received by the midbrain, which in the lowest vertebrates played a more important part than the cerebrum. Other senses were represented by other parts of the brain, but no one of them exercised such a dominating influence over the others as the cerebrum does in mammalia. Thus a low vertebrate, say a fish, might see an object and recognize it as desirable or otherwise, but this consciousness was not greatly aided by other senses. So the fish was deceived by an imitation fly, but per contra would pass by another object as not desirable for food because it did not look like a fly. In the same way a lizard or a frog, depending largely for its information on the sense of sound, might have its attention roused by the sound of the gentlest splash of water or the rustling of a leaf, but be quite undisturbed by the loudest noises in its immediate proximity. The organs of the senses in animals without a neopallium responded only to their appropriate stimuli—that is to say, according to evolutionists, to those impressions which had come in the course of evolution to possess a precise meaning for them. This seems to be a statement rather than an explanation—unless the professor expects everyone to attach a peculiar meaning to the word evolution, which many people seem to think is itself explanatory of everything.

Angina pectoris has been the subject of much correspondence and discussion for several months, though I can hardly say that there has been a definite contribution to our knowledge of its origin or nature. The Harveian Society last month devoted a meeting to its discussion and as this society has often done on other occasions elicited a number of opinions which furnish a sort of summary of the subject. The paper which began the discussion was by Dr. Alex. Morison, who said it was "a painful affection of the heart, as a whole depending on a disorganization in the anatomical character or disorder in the physiological function of one or more of the factors in cardiac action, and associated in some rare cases with a fear of impending death." All this may be a comprehensive description, but it is hardly a definition, as he called it. He was driven to the conclusion that the character and situation of the conditions which originate it vary, and the heart, like other viscera, is endowed with low sensibility in normal circumstances, but in lesions of the internal surfaces or irritation of the nerve supply may prove as sensitive as analagous viscera. Referred pain may arise in the intraaortic or intracardiac nerves. As to treatment, cases of so-called vasomotor angina with valvular disease tended to subside. Not so with nonvalvular cases, which might end fatally, and needed not merely nitrites but morphine, atropine, and general anesthesia to relieve and to arrest death.

Sir Clifford Allbutt considered the cause of uncomplicated cases to be disease of the aorta above the valves and the distribution of pain to depend largely on the part involved. He admitted a cardiac pain, situated in the precordial area, but this was distinct from that of the typical angina attack. Early specific treatment was most important.

Sir Douglas Powell held that typical angina was due to atheroma and thrombosis of the coronary arteries. Mere aortic pain following exertion was not angina. Rise of arterial blood pressure was also a factor and he had seen cases improve on the development of mitral regurgitation.

Sir Lauder Brunton compared the pain to that of a distended bladder. He thought in some cases it was due to increased arterial blood pressure, in others to spasm of the coronary arteries. He advised carefully regulated exercise and rest after meals.

Dr. James Mackenzie thought irregularities of the heart and exhaustion of the cardiac muscle were mostly present and the distribution of the pain should be investigated.

Dr. Lees mentioned as a confirmatory sign a dilated aorta. Heavy smoking was a factor. The nerve plexuses about the aorta needed investigation to help towards a pathology of angina.

Dr. Colbeck said the main factor was pain in the heart, and any explanation proposed should account for the fear of impending death.

Sir John Broadbent thought most attacks depended on spasm of vessels induced by cold or exertion.

Dr. B. Thorne thought the real cause was distension of the heart. Tender areas over the apex, the third costal cartilage, and lower part of the sternum could at times be felt, in which case he advised blistering.

Dr. Ewart thought respiration had not been sufficiently considered. Spasm of the diaphragm might sometimes account for the pain of an attack.

Another medical research fund is announced. The late Dr. C. Graham, professor of chemistry at University College, has left the residue of his estate, after various bequests, to found a fund to be called the "Charles Graham Medical Research Fund," to be applied in aid of any research by a teacher or student of University College for the prevention, cure, or alleviation of human disease or suffering. The power is also given of conferring a gold medal of appropriate value for certain

researches. The "Charles Graham student in pathology" will be appointed for two years and receive a sum not exceeding £200 per annum. His position will be analogous to that of the "Sharpey student of physiology" in the same school.

The Lord Mayor presided over the annual meeting of the Hospital Sunday Fund on the 17th. The support during the year was said to have been very good, although there was some loss in connection with Sunday collections in consequence of the death of clergymen who were zealous supporters. But the largest number of contributing congregations had been last year, viz., 2,070.

Progress of Medical Science.

Boston Medical and Surgical Journal, December 30, 1909.

Medical Expert Testimony.—G. W. Gay says that the adoption of the following propositions would improve the present unfortunate condition of medical expert testimony in our courts: First, give the court authority to charge the jury upon the expert medical evidence; second, give the court authority to appoint medical experts in certain cases upon his own motion, said expert to be paid by the county; third, refer all important questions relating to the mental condition of the parties at suit to a commission of alienists or experts before the trial; fourth, the bench and bar should correct certain abuses attending the hearing of expert evidence in the courts. The first two propositions call for legislative action, the last two do not.

New York Medical Journal, January 1, 1910.

Choroiditis Dependent Upon Appendicitis.—R. T. Morris describes a case referred to him for opinion, the physician sending the patient stating that he had choroiditis which was probably due to toxemia arising from a diseased appendix. This proved to be the correct diagnosis. Examination showed a typical case of fibroid degeneration of the appendix with the type of irritation, which Morris calls protective appendicitis. This form of appendicular trouble is not always harmless, and may cause chronic derangement of the bowel from its influence on the intimate ganglia of the bowel wall. In this particular it seemed to lead to persistent intestinal dyspepsia from lack of control of the growth of the intestinal bacilli. The appendix was removed through a short incision and was found to consist of an organ the inner structures of which had been replaced by connective tissue. The patient at once began to recover from his intestinal indigestion, from his general nervous irritability, and from his choroiditis. At the present time he considers himself perfectly well.

Is the Demonstration of the Gonococcus as Simple a Matter as Is Commonly Supposed?—This question is considered by Eugene Fuller, who says that it is to be hoped that laboratory methods can be devised to make certain the differentiation of the different groups of diplococci found in urethral discharges. He mentions two cases illustrating the difficulties in the light of our present knowledge. Diplococci seen away from or outside of the leucocytes do not count or are supposed to be other forms of organisms largely, perhaps streptococci. Since the inauguration of this teaching Metchnikoff's theory now established has been advanced that in infections the function of the white corpuscles is to digest and destroy the germs in question. Consequently the finding of diplococci in the leucocyte in the process of natural destruction can hardly be at present looked upon as characteristic of the gonococcus. After the Gram stain one cannot really be sure that he is again looking through the microscope at the same leucocyte in which he previously saw diplococci, so the failure to detect diplococci retaining colorization in an atypical or chronic case might easily lead one to draw a false conclusion, even though the Gram method were held to be accurate. If one sends a smear to a high class histological laboratory it is not unusual to get the report that diplococci have been found which present the appearance or characteristics of gonococci. In other words, the authority making the report does not express himself positively as an examiner less experienced would be apt to do. That same authority in reporting, for instance, the finding of tubercle never words his report vaguely. He then states positively that the organism found was the tubercle bacillus. In atypical cases the writer has been informed by recognized authority that cultures should be made of the diplococci discovered before an accurate diagnosis can be made. The accurate making of cultures in such cases could, of course, be entrusted only to a laboratory specialist. In medical teaching great stress has very properly been laid on the danger of the transmission of gonorrheal infection by those of either sex who have once suffered from the disease. Terrible examples of such transmission are constantly coming to the surgeon's attention. As a result just as constantly individuals consult surgeons in order to have the question of their freedom from the possibility of gonorrheal contagiousness settled. Such individuals represent the conscientious, careful, and trustworthy element in the community. The individuals who transmit contagion to innocent parties are drawn almost wholly from a different element. They represent the careless, indifferent, conscienceless class. With this latter class a gonorrheal attack is forgotten as soon as the active subjective symptoms connected with it have subsided, and, like the person who "thought the gun was not loaded," subsequent sexual relations are entered upon oblivious to the possibility of disastrous consequences.

Indiscriminate Enucleation of the Tonsil.—P. Fridenberg says that enucleation as at present performed by competent operators is so effectual in removing a diseased organ that it would be doubly deplorable if it should come into disrepute, but he fears that such may be the case unless the zeal of the moment in this respect is restrained and we learn to perform the operation in proper instances only. He questions whether the removal of the tonsil with its capsule is either safe or useful in most cases. We know so little of the physiology of the tonsil, and especially of its capsule as a possible protecting mechanism, so little as to its part in so important a function as voice and tone production, that its complete removal, except for valid cause, must be earnestly deprecated. There are cases of submerged, adherent, irregular, or cystic tonsils, in which recurrent attacks of inflammation, evident disease, or extreme susceptibility to the acute exanthemata and infections of the upper respiratory tract, from colds to influenza, supply an operative indication which, quite in contradistinction to the factor of obstructed respiration, calls for radical removal of a source of infection, and not for more air space. Let enucleation of the tonsil, whether by finger or separators, by snare or scissors, be reserved for these cases. While there is no excessive hemorrhage, there is much traumatism, marked reaction, a slough which lasts for some time, and pain on swallowing which may not entirely disappear for a week or two. In at least one case of which the author has heard, extensive adhesions formed which glued together the pillars of the fauces on one side, with disastrous results for a previously beautiful singing voice.

A Comparison Between Clinical Infection and Experimental Inoculation in Syphilis.—D. Montgomery says that although man is most susceptible to the disease, his tissues are not equally so. The rete Malpighi and the immediate underlying papillary layer of the corium are especially vulnerable. There must be a wound in order to inoculate. The blood of the veins does not seem to have the power of destroying spirochetes possessed by the blood of the arteries. Next to coitus, the habit of kissing promotes the spread of the disease. It is extremely unlikely that the ordinary drinking cup communicates the virus unless there is a wound on the gums or lips, against which the cup is forcibly pressed. Wounds made by a barber frequently communicate the poison. Close shaving in a man with seborrhœic eczema is liable to occasion erosions. Barbers close wounds with silver nitrate sticks which may be covered with specific virus. Chancres on the hand in medical men are quite common. They occur either on the index fingers, especially about the nail, or on the web between the thumb and index, or between the index and the medius. The act of digital examination of the vagina puts these webs on the stretch, and naturally opens the lips of any wound or crack that may be present. Then again if the nail fold is not kept well pressed back, the forward growing nail naturally pulls on it, giving rise to hangnails of just such character as are best adapted to the introduction of the syphilitic virus. It is furthermore a well-known fact that infections on the dorsal surface of the fingers and hand are much more frequent than those on the palmar surface. Any lesion, therefore, about the nail, or on the back of the index fingers, or on the webs between these fingers and their neighbors, when occurring in obstetricians or gynecologists, should be viewed with suspicion, and if at all suspected, should be examined for spirochetes. Obstetricians are, of course, more liable to this class of infection even than gynecologists, because their patients are in the midst of full sexual life, and therefore are especially liable to have fresh, readily inoculated syphilis. From a natural history standpoint, this infection means that Nature here exhibits her usual care in the preservation of the type, together with absolute indifference for the individual. In

this instance the care is directed to the preservation of the *Spirochæta pallida*. Here we have an organism so selective in its habitat that it is practically limited to getting its food from one species of animals, from man. It thrives wonderfully well on man, and on the anthropoid apes, but is with difficulty transmitted to any other animal, and when so transmitted it has a precarious and short existence. The original geographical location of the disease was America, and to get to the chimpanzees in West Africa would have been impossible for an organism having such poor means of progression as the *Spirochæta pallida*. And, furthermore, to maintain itself among a sparse, thinly settled group, such as the anthropoid apes, would have been very difficult. It is therefore limited to man, and to secure its existence and due propagation it is hitched to man at the most active stage of his existence, and is ingeniously associated with one of his two strongest desires at this time of life, the sexual desire.

Journal of the American Medical Association, January 1, 1910.

The Therapeutic Utilization of Biliary Fistulas.—L. L. McArthur, having noticed the loss of water in irrigating biliary fistulas, conceived the idea of studying the effects of various fluids introduced through this route into the duodenum. First, as a means of deluging the system with water, he found that a temporary fistula may often be utilized with surprisingly good effects. He has repeatedly injected in such cases, by continuous irrigation of a warm salt solution, up to 3,000 c.c. of fluid as a means of flushing out the kidneys, clearing up a jaundice, or filling up the blood vessels, and in one case even added dextrose as supplying the food calories most readily assimilable. He is not recommending a cholecystostomy as a therapeutic measure for other ailments than those for which it was originally designed, but simply the utilization of already existing fistulas for indications similar to those mentioned.

Appendicitis.—L. G. Guerry reports his experiences with a consecutive series of 545 cases of appendicitis operations with only two deaths, these occurring in the first 100 patients operated on. This experience proves, in his opinion, that there is a factor in the surgical mortality that is not fully appreciated or provided against. In this total of 545 there were 240 chronic cases calling for an interval operation, with no deaths, as might have been expected. Of acute cases 92 patients were operated on within thirty-six hours. His rule, so far as he has one, is, he says, to operate as soon as the diagnosis is made, provided it can be made within thirty-six hours. After that the pathological conditions are different; the third and fourth day cases are the ones that furnish the mortality statistics. Guerry holds that there is a definite tendency to localization in cases of appendicitis complicated with suppuration; there were 213 cases of this kind in the series; 68 of these were first seen on the third or fourth day of the disease. The pulse in most cases was 135, temperature 104° F. Vomiting, distention, pinched features, and some delirium were also present. None of these patients was operated on at once, but all were treated according to the Ochsner method, which he thinks is life saving, at least in the practice of the ordinary surgeon and practitioner. Guerry emphasizes the fact that none of these patients was operated on immediately and none died. It must, he says, have been genuine insight in Ochsner to recognize that the chief factor in dissemination of the peritoneal infection is the vermicular movement of the small intestine and that physiological rest is the rational treatment of the diseased process, thus enabling nature the chance she seeks to localize the disease. Gastric lavage, also, is rational, as it carries off the regurgitated contents of the small intestine and favors the attainment of physiological rest of both organs. Guerry does not wish to be considered extreme, but he desires to emphasize the importance of utilizing and aiding the natural forces, and of using surgical discrimination and judgment in these cases In almost all cases he operated through the McBurney incision; when drainage is needed he drains through a stab wound to one side. The rule is to remove the appendix, but there are exceptions to this rule. He believes it better to enter the peritoneal cavity by Ware's modification of McBurney's method, pack off the infected area, and remove the diseased tissue. One of his patients who died had renal tuberculosis and succumbed on the eighth day with postoperative anuria. The other fatal case was that of a child who had been ill ten days and died of a continuation of the peritonitis.

Cutaneous Syphilis.—A. Ravogli publishes the results of his studies, microscopic and otherwise, of the proliferating growths of syphilis. He remarks that in a short article on elephantiásis (*Jour. Cutan. Dis.*, 1906) presented to the American Dermatological Association, he had maintained the luetic origin of this condition when occurring in the genitals, in many instances. He also held that all cases of elephantiasis are started by the presence of infectious germs or of parasites causing irritation and lymph stasis. He goes at length into showing how the germ of syphilis acts in producing vegetating papillary growths, etc. His microscopical findings are illustrated and he comes to the conclusion that the proliferating masses of the tertiary syphilitic ulcers show no special characteristics, but have common characters with the proliferations of other morbid processes. The imbibition of the tissues from the lymph stasis, the hypernutrition of the connective tissue corpuscles, cause their division and their proliferation. The normally limiting elastic fibers are gradually lost and the collagenous elements are left free to proliferate without restraint. That the spirochete is a starting point cannot be doubted, as they are shown in the secondary vegetating patches. In the tertiary they were not found, but this does not disprove the above assertion. It is possible they are not so readily stained or may be concealed in the deeper tissues. As regards treatment, it is not difficult to cure the secondary proliferated patches by internal constitutional treatment with external application of calomel or solution of mercurial chloride, one to five hundred. In some cases strong caustics may be necessary. In some cases other measures, like the use of iodide, local bathing with bichloride solution, one to one thousand, and local applications of mercurial plasters have been satisfactory, while in others extensive curetting was required.

Sea-Water Treatment.—T. LeBoutillier recommends the use of the Quinlin treatment in certain conditions of malnutrition, marasmus, and chronic indigestion in infants and children. He finds that there is an improvement in appetite in other children and relief of colic in infants, together with improvement of weight and muscular strength and ability to digest food. The subcutaneous injection of sea-water solution is not accompanied with the pain and other disturbances frequently following serum injections. The sea-water was obtained well out at sea and from a sufficient depth to insure against contamination by surface bacteria. He followed the Roberts Simon method, diluting 83 parts of sea-water with 190 parts of pure spring water, filtering through a germ-proof Berkefeld filter, and putting it up in sterile bottles. The usual injection sites are just below the angle of the scapula or in the gluteal regions, the former being preferable as less liable to contamination in children. The amount injected varied from 10 to 60 c.c., the usual dose being 15 to 30 c.c., according to age and urgency of the case, and from three times a week to every day for a short time. Sometimes five or six injections improved the condition so much that the patient was discharged. In other cases the treatment had to be kept up for several months. Effects on nutrition especially noted in his thirty cases are as follows: There is a slight increase in the amount of urine following the first few injections, in many instances there is improvement in the condition of the stools without any change in the diet. He considers this fact significant. There is improvement in the appetite and in the amount of food taken within the first two or three weeks; this is noticeable in older children suffering from malnutrition or chronic indigestion. In infants with distressing colic he has found this invariably relieved within the first two weeks. The skin in many cases was in the beginning harsh, dry, and more or less scaly. This cleared up entirely, whether in infants or in older children. The patients who were losing weight or stationary, as a rule gained after the first few treatments, sometimes as much as an ounce a day. In one or two cases there was an initial loss, but this was rapidly made up. The sleep of many patients was markedly improved. Two cases of marasmus illustrating the effects of this treatment are reported. The claim of French investigators that sea-water is more rapid in its action and induces a greater gain in weight than artificially made solutions is noted. The author does not verify this from his own experience, but he is making experiments with tablets made up with normal saline solution proportions and containing

sodium chloride, grains 34¾; calcium chloride, grain 1, and potassium chloride, grain ⅜. The treatment has suffered somewhat from being overpraised. The author considers it, however, a useful adjunct of other methods in the malnutrition of tuberculous disease or that following any of the infectious diseases. It does not dispense with hygienic, dietetic, or medical treatment, but should be used only for its tonic and stimulative action on the body cells.

The Work Cure.—H. J. Hall gives an account of an establishment started by him and carried on now for five years in which manual occupation is utilized in the treatment of neurasthenia. He says the normalizing effect of suitable manual work, or even of well-chosen intellectual work, on the neurasthenic or psychasthenic who has been idle or overworked, is very evident. The difficulties, however, in inducing the patient to exert himself and in selecting the proper work have made progress along these lines rather slow. Unfortunately it is true, also, that ill-advised work may be productive of positive harm and intensify all the symptoms. He had felt for a long time that an adequate study of the subject could only be made in an institution specially devoted to this purpose. He therefore established five years ago a small workshop for the making of hand-woven fabrics and has since added a number of artistic occupations, such as wood carving, metal work, and pottery manufacture, and the experiment has been fully justified. These crafts were chosen because of their universal appeal, their essential dignity, and the fact that they could be very gradually learned and proficiency in them would be valued by the patient. The patients as a rule enjoy the novelty of the treatment and are diverted more or less from their worry and suffering. From the first the patient is taught to economize strength and the simplest mechanical acts were often chosen at first and repeated until they could be performed without mental and physical fatigue. Gradually the difficulties and requirements of the work are increased, the essential point being an economy of nervous energy and the maintenance of a simple and direct mental attitude. Ample opportunities for rest are given, and for the necessary medical treatment, but no attempt is made to carry out the elaborate treatment of the sanatorium. If the patient is to be fully restored to usefulness he will have to give up these aids, and the earlier the better. Hall finds that the hand weaving is most valuable in the treatment, giving immediate and tangible results, and not requiring too close use of the eyes. Wood-carving comes next, especially for beginners, as it gives opportunity for broad free-arm movements as a balance to the finer closer work. Metal work is perhaps the least useful therapeutically, but it has a special value in certain cases. The pottery has developed rapidly and has been perhaps the most successful in its results, though most of the work has been done by the craftsmen rather than by the pupils. He gives a tabulated statement of the result as regards recovery. Improvement occurred in all cases and complete relief in 14; 91 of his patients were women. The conditions treated ranged from actual phychoses and insanity through hysteria and severe neurasthenia to the milder types. The insane cases were only received at the beginning. Two were improved, two very much improved, and one cured out of a total of five. It is not intended nowadays to receive any cases of insanity. Relapses have been very few among the patients. It should be added that the shops have been employed by some persons who were not ill, but wished to learn the handicrafts. Steps have been taken to establish a training school where nurses can learn the methods and extend their usefulness in private families or in other institutions. The establishment has been a serious financial burden and a great consumer of the physician's time, but is now nearly on a self-supporting basis. He finds that the ideas embodied in the work appeal, as a rule, not only to the profession, but to the patients themselves and to the people at large.

The Lancet, December 25, 1909.

The Effects and Use of Radium.—D. Turner reports six cases, three of rodent ulcer all cured, two of angioma both cured, and two of carcinoma, one cured and one still under treatment. Other conditions for which he has used radium are warts, lupus erythematosus, plain lupus, leukoplakia, and pruritus. He describes the apparatus he has employed, and says the radium appears to have two chief actions: (1) as a specific action on certain pathological condition as rodent ulcers, cancerous nodules, angiomas, keloids cicatrices, and fibrous contractions; and (2) an action producing inflammation and destruction somewhat similar to that produced by caustics and burns. Sometimes the one and sometimes the other may be used or they may be combined. The curative action of radium on rodent ulcers is an example of its specific effect. After a sufficient exposure the floor of the ulcer will be observed to fill up, the raised edges to subside, the surface to contract until the part will be covered with fresh, rather transparent skin. As a rule, no pain at all will be felt, and there may be but little inflammation, but the part may dry up under a scab. If radium be applied to a skin area in sufficient dose, there will be observed in the course of from a few hours to some days an area which will become slightly raised and a little tender. Over this a scab may form resembling, as has been pointed out, impetigo. This may last for some time or be replaced by another. The dose of radium ought to be measured by the product of the strength of the preparation and the length of exposure —what would be termed in electricity, ampère hours—but these quantities would be modified by the presence of screens.

The Vaccine Treatment of Pyorrhea Alveolaris.—K. Goadby says that cases of suppuration of the alveolus may be divided into: (1) those which exhibit some constitutional evidences due to intoxication or bacterial invasion, and (2) those which have no constitutional symptoms but have from time to time pathological manifestations about the oral mucosa. Following the author's classification, we make the following types: (1) the teeth are not loose and gums appear normal. Careful examination will show a little pus between the teeth, showing the interdental bone has already become affected. (2) The gums bleed easily and the interdental spaces are enlarged. (3) The hypertrophied gum becomes shrunken, bone removed between the teeth, patches of rarefying osteitis are scattered about the alveolus, and the bone thinned so that a needle may be passed through it at the tooth-root level. (4) The teeth are all loose in their sockets, the gums are boggy, the alveolar process has become absorbed, and the breath usually has a marked fetor. In the author's experience a cure has followed many cases with the vaccine treatment, a specific vaccine being prepared from a given case, the one chosen for therapy being the one which showed a deviation from the normal in the opsonic index to the patient's own serum. As a rule, constitutional symptoms after employment of the vaccine have been wanting. Occasionally vomiting, acute headache, and general malaise have ensued. It is not uncommon when the *Micrococcus catarrhalis* is employed as a vaccine to get a disturbance closely resembling an acute coryza, particularly in persons who are subject to colds in the head. Locally, surgical methods yield the best results. The actual cautery has seemed to act best. It should be undertaken after immunization has been secured. Lymphatics are sometimes enlarged, but this need not stop the treatment. Treatment necessarily covers a long time. Care should be taken before beginning treatment to ascertain the stage to which the pathological process has progressed.

British Medical Journal, December 25, 1909.

Diver's Paralysis.—G. Blick says that the points that have impressed him in connection with diver's paralysis are the following: First, signs of asphyxia are nearly always present. It would appear from this that in the rapidly fatal cases death is largely due to affection of the breathing centers. Second, in roughly two per cent. of the cases in which death is not immediate, meningitis set in in about a week. In this respect, however, considering the damage done to the nervous centers the only wonder is that it is not a more frequent occurrence. Third, the question arises as to the cause of the congestion found on autopsies of fatal cases. Is it due to over-expansion of the vessels by gases suddenly released from pressure or is it simply part and parcel of the condition of asphyxia? From concomitant appearances in the thorax it would appear that the latter is the true explanation. Fourth, the paralysis of the bladder and loss of power of micturition are constant and occur in cases so slight that it is practically the only symptom calling for attention. Patients often walk to the hospital for catheterization. Fifth, the apparent point of selection for the most striking lesions of this disease is in the cervical cord. All of the large cordal hemorrhages found could be covered by three cervical vertebræ. Two explanations are suggested for this localization, the comparatively large size and motility of the spinal canal at this point and the fact that this portion of the cord is movable in the metal helmet of the diver, the rest of the body being covered with the rubber dress, closely pressed to the body by the water pressure.

Theoretically there is nothing to choose from the pressure point of view. Is there anything in the movement? It must he remembered that a diver's dress at a great depth precludes bending the back beyond a very slight degree.

The Uses of Catgut in Surgery.—This question is considered by C. Y. Pearson with special reference to iodine catgut and iodine-formalin catgut. His general conclusions are as follows: First, the use of simple aseptic catgut is unsafe no matter how it is prepared. Second, iodine catgut may be used safely in all cases in which a quickly absorbable suture or ligature will answer. Third, the use of iodine-formalin catgut is indicated when slower absorption of the ligature material is desired and if prepared in the manner stated by the author it may be used in all those instances in which it has been customary to use chromicized or sulphochromic catgut. Fourth, the operating surgeon should be personally responsible for the manner in which any catgut he uses is prepared. The mode of preparation recommended is as follows: The catgut is laid in an alcoholic solution of iodine. At the end of eight days it is removed with sterile forceps, placed in a sterile jar, and washed with either a weak solution of carbolic acid or with running water to remove the alcohol and iodine from the outer layers and to permit more freedom for the action of the formalin. Then it is placed in a three per cent. formalin solution for from 24 to 48 hours, according to the thickness of the gut, washed by running water for a few hours to remove the formalin, and finally placed in 50 per cent. alcohol containing one-half per cent. iodine and 5 per cent. glycerine, the latter rendering the gut more pliable.

Indications for Immediately Opening the Abdomen in Acute Cases.—Among the conditions enumerated by W. G. Spencer are hernia, appendicitis, gastroduodenal ulceration and perforation, gangrene of the gall-bladder, acute pancreatic abscess, twisted ovarian cysts or dermoid, salpingitis, hematocele, extrauterine pregnancy, streptococcal infection following abortion, intestinal obstruction, abdominal injuries, cesarean section, and renal obstruction with suppression of urine. Abdominal surgery can, as a matter of fact, be well done in private houses, and it will be found that Lord Lister's well-known directions contain all the essentials for successful surgery. In our large hospitals, in which one case closely follows another into the operating theater, the many elaborate suggestions of bacteriology are necessary to prevent infection. The author discusses various noted points in the lesions named and defines his own course in the various clinical emergencies.

Berliner klinische Wochenschrift, December 13, 1909.

Nitrites, Nitrous Acid, and Nitrous Oxide as the Poison in Cholera.—Emmerich answers Hyman van der Bergh and Gutterink in their recent article in which they were unable to substantiate Emmerich's theory that the symptoms of Asiatic cholera were due to the absorption of nitrites from the intestines. The argument is too involved for an abstract, but the main points are that though methemoglobin was not demonstrated spectroscopically by van der Bergh, nevertheless the brown color of the blood in cases of cholera proved that it was present. The formation of lactic acid by the cholera vibrios changed the nitrites into nitrous acid, which injured the intestinal wall and aided in the absorption of the poison.

Münchener medizinische Wochenschrift, December 7 and 14, 1909.

The Etiology of Acute Anterior Poliomyelitis.—Paul H. Römer has made careful bacteriological and inoculation experiments with the tonsillar culture, cerebrospinal fluid, cord and brain substance, etc., of a series of cases of poliomyelitis. His results were largely negative. He concludes that the cause of epidemic infantile paralysis in all probability does not belong to bacteria which can be stained or cultivated easily. This virus occurs in the brain and cord of the infected individuals, and may be transmitted to monkeys by intracerebral, and, according to Knöpfelmacher, by intraperitoneal injection. In case of experimental monkey poliomyelitis the disease may be carried to other monkeys. In this way an artificial cultivation of the virus may be produced in time.

Treatment of the Early Stage of Acute Anterior Poliomyelitis.—Hohmann calls attention to the great hypersensitiveness of the spine often occurring in the early stages of poliomyelitis, and reports two cases in which this was relieved promptly by putting the child up in a plaster jacket. He says that further observations are required to determine whether this absolute rest of the spine has any actual effect upon the course of the disease or is only symptomatic.

The Significance of Coagulation in Controlling Postpartem Hemorrhage.—Neu has carried on a series of experiments as to the influence of coagulation of the blood in postpartem hemorrhage and the factors which control it. It was previously considered that thrombi found in the uterus in the neighborhood of the placenta were of pathological import. Neu attempted to prove that these were physiological and one of Nature's methods of controlling hemorrhage. He accepted the two premises that the addition of serum from animal tissues increased the coagulability of blood, and that the thrombokinase which did this was not free in the blood but confined to the tissue cells. All other necessary elements for coagulation, fibrinogen, calcium, and thrombogen occur in the blood, but to produce coagulation thrombokinase must be added from the tissues. To prove that thrombokinase was contained in the placental tissue he rubbed this up with normal saline. On addition of 0.4 c.c. of this extract to a definite amount of fresh blood complete coagulation occurred instantly, whereas the controle blood required from 18 to 20 minutes under identical conditions. Similarly, coagulation occurred five times quicker in blood dropped upon the fresh placenta wound of a dog. He concludes that while the most important factor in stopping postpartem hemorrhage is muscular contraction, that nevertheless the presence of the thrombokinase liberated from the injured decidua cells and vessel endothelium, by stimulating coagulation, also aids in the hemostasis.

Zirconium Oxide as a Producer of Contrasts in Roentgenology.—Kaestle says that a chemical substance to be used in the organs to produce *x*-ray shadows must have the following characteristics: (1) It must not, as a result of chemical charges, cause either local or constitutional injury to the person of the patient; it must pass through the gastrointestinal canal unchanged. (2) Its absorptive power for *x*-rays must be as great as possible. (3) The preparation must be free from odor or taste, and the color must be such that it may be mixed with some common article of diet. (4) It must be cheap. Owing to the numerous cases reported of bismuth poisoning, the salts of bismuth do not fulfill the first requirements. Iron oxide, which has been recommended more recently, is objectionable on account of its color and its lower degree of absorption of the *x*-rays. The author has been experimenting recently with zirconium oxide as a substitute. He had previously tried thorium oxide, but found this, though efficient and harmless, to be too expensive for practical use. The zirconium oxide is a white, odorless, tasteless salt, quite insoluble except in hot sulphuric acid. The powder is entirely unchanged in the animal organism. Subcutaneous injections of the salt into animals showed it to have no toxic action whatever. The injected animals gained in weight, and no albumin or casts could be found in the urine. Animals killed after the injections showed no pathological changes. The author believes that in zirconium oxide we have an ideal substance for *x*-ray work. Its absorbent power for the *x*-ray is good. It is much greater than that of iron oxide and scarcely below that of bismuth. Owing to its white color and the possibility of pulverizing it easily, it can be added to a porridge and will be taken by the most particular of patients. As a routine the author recommends that 150 to 200 grams of the salt and 200 grams of bolus albus be added to one liter of lukewarm water. It is inexpensive. It costs but 11 marks ($2.75) per kilo, or about 85 pfennigs (21 cents) for sufficient for an examination of the stomach.

A Rare Case of Nicotine Rash.—Näcke reports the case of an insane patient who drank a cup of coffee in which he had steeped 7 to 10 grams of chewing tobacco. Acute nicotine poisoning resulted, with nausea, vomiting, vascular and pupillary symptoms. Immediately afterwards an intense general erythema appeared with marked itching. This lasted 5 days and disappeared without peeling. There was no fever, albuminuria, or gastrointestinal symptoms. It was of interest that during the height of the rash the mental condition cleared up markedly, but rapidly relapsed after the recovery of the skin symptoms.

Exomphalos.—I. F. Hicks reports a case of umbilical hernia in a new-born infant. On the eighteenth day the child was operated on for strangulation at the umbilical ring, with invagination and adhesions. Six or eight inches of the ileum were resected and the ends of the divided intestine brought together and united by Lembert sutures. The mesentery was stitched where a V-shaped portion had been removed. The bowels were kept locked by opiates for six days, when the infant had a natural evacuation, and since then an uneventful recovery.—*Journal of the American Medical Association.*

Book Reviews.

Schemata zum Einzeichen von Kurven bei Stoffwechselkrankheiten. Von Dr. Hermann Schall und Dr. August Heisler, Assistenten der Medizinischen Universitätsklinik Marburg a. Lahn. Würzburg: Curt Kabitzsch (A. Stubers Verlag), 1909.

An evidence of the widespread interest in metabolic disorders is shown in the publication of these very excellent charts, which permit the recording in convenient fashion of body weight, the amount of urine, the excretion of sugar, sodium chloride, albumin, and uric acid, and, in the form of curves, the intake of water, carbohydrate, protein, and fat. One chart will do for a period of six weeks. It would be difficult to conceive of anything more satisfactory for the specific purpose.

Spezielle Dietetik des Lungen- und Kehlkopf-Schwindsuechtigen. Von Dr. Felix Blumenfeld, Wiesbaden. Berlin: Verlag von August Hirschwald, 1909.

This is an enlarged and improved edition, in which Dr. Blumenfeld considers the various kinds of food applicable in tuberculosis, general sanitary care of the body, therapy of special symptoms and complications, general climatic and psychical therapy (a chapter of unusual interest), and other pertinent matters. Nothing new is presented, but the work as a whole is an excellent one, from which a physician caring for tuberculous cases may derive much practical information.

Leucopathies, Métastasea, Albuminuries, et Ictères Leucopathiques. Par le Dr. Émile Feuillié, Ancien Interne en médecine des hôpitaux de Paris; Médaille des épidémies (Dunkerque, 1908), Pharmacien de 1re classe; Licencié et sciences physiques; Stagiaire de l'Académie de médecine aux Eaux Minérales; Préparateur à la Faculté de Médecine. Paris: G. Steinheil, Éditeur, 1909.

The monograph is devoted to experimental studies to show that leucocytes are endowed with the power of emigrating into the tissue in order to escape circulating toxins, and are then capable of following these toxins as they are excreted, for example, into the tubules of the kidney, and there absorbing the toxins and being thrown off from the body through the tubules in the form of leucocytic masses or leucocyte casts. Apparently, the author considers that it is important for the body to eliminate the poisoned leucocyte rather than to destroy it in the tissues. Some inconclusive animal experiments and clinical histories are offered to prove this thesis. The author thinks that the cells of the renal tubules never appear in the urine, but only leucocytes, and that the cylindrical cells are leucocytes, not casts composed of renal cells. Albuminuria, he thinks, is often due to exudation of leucocytes solely. He thinks that edema is possibly due to destruction of leucocytes and the anaphylactic phenomena have the same basis. Several colored plates are introduced to illustrate some of the lesions of the kidney supposed to be due to the emigration of leucocytes.

The Dietetic Treatment of Diabetes. By B. D. Basu. Published by the Panini Office, Bhuvaneshvari, Ashram, Allahabad, 1909.

The pamphlet is a semi-popular one on the treatment of diabetes. It is not without errors, as, for instance, when the statement is made that: "There is no constant proportion between the sugar and nitrogen of the urine, and so the origin of sugar from proteid is doubted." On the other hand, there is a good deal of very sensible advice concerning the nature and amount of food suitable for the diabetic, in some instances giving the details of methods of cooking. It should be especially helpful to patients who are on a diabetic diet.

Diagnostic Methods: Chemical, Bacteriological, and Microscopical. A Text-book for Students and Practitioners. By Ralph W. Webster, M.D., Ph.D., Assistant Professor of Pharmacological Therapeutics and Instructor in Medicine in Rush Medical College, University of Chicago; Pathological Chemist of Cook County Hospital, Chicago. With 37 colored plates and 164 other illustrations. Philadelphia: P. Blakiston's Sons, 1909.

In estimating the value of a new book on chemical, bacteriological, and microscopical diagnostic methods employed in medicine and surgery, it is inevitable that comparison should be drawn between the new volume and those previously in the field, in order to see whether it possesses any point of superiority over its predecessors. From this aspect the general make-up of the volume, the binding, paper, and type are excellent. An especially useful feature is the setting off of each subject paragraph by the use of large heavy-faced type, not run in with the headline. There are, however, a great many omitted and broken type throughout the text, for which the author is hardly responsible, and which it is difficult to avoid in a first edition. One general criticism which may be offered is that forty-two of the plates have been transferred from Tyson, and many others from Hawk. This, of course, is an easy method of obtaining cuts and is satisfactory from the publisher's point of view because of the low expense. But in getting out a book of this type it seems only right that the illustrations of the more frequent parasites, crystals, and apparatus should be freshly drawn, or, better, photographed. The colored plates, on the other hand, are very largely original, and, on the whole, can be highly commended, though, of course, the color reproduction is not so satisfactory as in the finer lithographic plates we are accustomed to see from Germany. Some, as, for instance, the plate given up to *Streptococcus pyogenes* (pyrogenes in the plate) could have been very properly replaced by a half-tone photomicrograph costing much less than the inset plate. The colored plates of the blood are perhaps the most satisfactory.

To take up the different parts in detail, the volume begins with a chapter on the sputum, which is satisfactory in every way. The section on searching for the tubercle bacillus is especially good, the writer calling attention to the necessity for care in determining the specific gravity of the fluid from which tubercle bacilli are obtained by centrifugalization, to the fact that not all acid-resisting bacteria are tubercle bacilli, and to the advantage of separate staining and decolorizing for the preparation of the ordinary smear slides. He is also right in insisting on the necessity for inoculating guinea-pigs in doubtful cases. In the next chapter, on the secretions from the mouth, nose, and conjunctiva, the recent morphological studies on the trachoma bodies are introduced, though the matter is still unsettled.

In the chapter on gastric analysis, Uffelmann's test is rightly described as unsatisfactory. Töpfer's method of determining the acids is given as the most satisfactory for clinical purposes, as is undoubtedly the case, the criticisms of its slight inaccuracies being based upon the common delusion that the stomach secretes a mathematically exact amount of hydrochloric acid in each of the varying nervous and physical derangements of the body. In estimating pepsin, the new edestin and ricin methods are quite properly not admitted, as there is still some doubt whether they will prove satisfactory for general use. They are certainly still in an experimental stage, and the use of a toxic substance such as ricin about the laboratory is questionable.

In the chapter on the feces, the blood tests are very fully considered, and the author has shown a commendable restraint in limiting himself to the standard, thoroughly tried procedures, and has not run after all the evanescent methods which appear almost weekly and are shown in about as short a time to be utterly unreliable. The diagnostic limitations of the chemical methods of studying the feces are properly emphasized. Mention of Janeway's recent finding of the *Trichina spiralis* in the blood of man is an illustration of the thoroughness with which the recent literature on parasites has been searched.

Perhaps the strongest chapter is that on uranalysis, in which the reviewer has failed to find anything for serious criticism. It is very full; the more valuable of the recent analytical methods are given; and the importance of being extremely cautious in drawing diagnostic hints from microscopical examinations alone is fully kept before the reader.

In regard to the Wassermann reaction, the *Spirochæte pallida* and the opsonic index, the writer takes a justifiably conservative position, which the profession at large would do well to imitate. On the whole, the book may be characterized as one of the best on the subject, if we except the illustrations. The author has successfully steered between the dogmatism of the quiz compend and the voluminous obscurity of the German monograph.

Klinische Mitteilungen aus dem Gebiete der Ohren- und Nasenkrankheiten für Studierende und Aerzte. Von Dr. Victor Lange, Kopenhagen. Berlin: Verlag von S. Karger, 1910.

This is an interesting collection of thirteen papers on various topics connected with nose, throat, and ear disease, and is not in any sense a connected textbook. Of special interest we note those on "Adenoids and Enuresis," "Intermittent Otalgia," and "Some Rare Cases of Idiosyncrasy to the External Application of Various Remedies." All are interesting. The book is printed with unusual clearness.

Society Reports.

NEW YORK ACADEMY OF MEDICINE.

Stated Meeting, Held December 16, 1909.

THE PRESIDENT, DR. JOHN A. WYETH, IN THE CHAIR.

The Pellagra Problem, Past and Present.—Dr. W. J. BABCOCK of Columbia, S. C., read this paper. Two years ago pellagra was but the shadow of a name to most of them, while to-day the health authorities of the National Government and of at least twenty-two States were engaged in the endeavor to solve the mystery of its origin, prevention, and cure. In 1735 Gasper Casel of Spain described an erythematous condition prevalent in the Asturias under the name of lepra asturiensis, and this really was the starting point for the authentic study of what was now known as pellagra. There were several apochryphal references to a similar malady. Barnino in 1600 described a pellagroid condition in the American Indians which was attributed to eating Indian corn. In 1771 Frapolli adopted the name now given to this disease. Italy, Spain, and France had been studying an erythematous condition for over a century before its complete identification as one and the same condition was recognized. This was due to the fact that the most striking feature of the condition objectively was the dermatitis, but clinically this was the least important symptom. Pellagra was not a skin disease, but was a constitutional disease as much as was smallpox. In 1776 resolutions were passed by the Board of Health of Venice to regulate the persecution of pellagra; they were based upon the assumption that the malady was caused by spoiled corn. The first record of observation of pellagra made by an American physician was by Dr. Earle of New York; he made references to cases in 1839 that he had seen in Milan. It was believed now by medical officers of the insane asylums of Georgia and South Carolina that pellagra had been present for at least thirty years in these institutions although unrecognized. Dr. Babcock described the work done in the study of this disease in these States. A committee, of which Assistant Surgeon-General Kerr of the United States Public Health and Marine Hospital Service was chairman, was now at work investigating pellagra. The evidence already at hand pointed emphatically to the existence of an epidemic of pellagra at the present time. Pellagra therefore must be recognized as an endemic malady which had of recent years assumed epidemic proportions. Among predisposing causes Babes mentioned innate weakness or anomalies of the nervous system. Lombroso placed cretins and epileptics as among those predisposed by nature to pellagra. Mild mental symptoms, melancholy and even neurasthenia preceded pellagrous attacks. Heredity had a certain influence. The association of pellagra with corn was based upon: (1) The fact that pellagra had followed the introduction of corn into European and African countries. (2) Pellagra was endemic only in corn-eating countries. However, it should not be forgotten that there were vast corn-growing areas where the disease had not been recognized. (3) People who did not eat corn products were free from pellagra. (4) A diminution of the use of corn products caused a corresponding lessening of pellagra and *vice versa*. Two recent French writers, Nicholas and Jamhon, had abandoned the corn theory, sound or mouldy, and tended to consider pellagra as a symdrome of diverse origin among which alcohol and poverty were of prime importance. In Italy certain writers attributed pellagra to intoxication by penicillum glaucum, or cryptogams allied to it, or to their toxic products developed on corn or other cereals. Dr. Babcock had known pellagrins to make homocidal attacks upon other patients and attempts at suicide were almost as symptomatically characteristic of this affection as they were of melancholia. In regard to prophylaxis Dr. Babcock quoted Dr. Lavinder to the effect that evidence of the communicability of pellagra was insufficient to warrant quarantine measures in the present state of our knowldege and that one must take cognizance of the connection between corn and pellagra in efforts at prophylaxis as new theories in regard to the etiology of the disease had not been definitely proved.

The Symptomatology, Pathology, and Treatment of Pellagra.—Dr. J. J. WATSON of Columbia, S. C., read this paper. He said that the malady was so insidious in its onset that it was difficult to state what were the earliest premonitory symptoms. The first thing usually complained of was some gastrointestinal disturbance, such as loss of appetite, burning sensation in the epigastrium, excessive desire for food and drink, or more often diarrhea with more or less stomatitis and salivation. Soon the patient felt disinclined to exerting himself. The characteristic symptom of the disease was the erythema on the hands and arms not covered by the clothing. The skin eruption might be either dry or wet. The eruption began as an erythema on the backs of the hands and extensor surfaces of the forearms, extending up the arms to the point where the sleeve reached, and there ended abruptly, being absolutely symmetrical if the sleeves were symmetrical, which was usually the case. Patients who were unable to work, and who sat about and held their hands, had the eruption on the flexor surface to the same extent as on the extensor surface. The erythema lasted a few days, and then began to fade and the skin to desquamate in fine scales if the dermatitis had been mild. As the redness faded the site of the erythema assumed a somewhat cyanotic hue. This was gradually replaced by a characteristic light liver or chocolate color which could not be mistaken or confounded with any other skin disease when once seen. In negroes it was readily recognized by an increase in the pigmentation, the site of the eruption appearing as though soot had been smeared on that part of the hand and arm. After a time the eruption scaled off and left the hands soft and glistening. The erythema later would again appear and the eruption would follow the same course as before. This might happen several times during the summer. As a result of these repeated inflammations the hands became hard and wrinkled and frequently deep fissues occurred on the fingers. In those who went barefooted, the feet and legs did not escape. The eruption appeared in the spring months and persisted until July, August, and September; it then disappeared to make its appearance in the following spring. In some cases there was a mild relapse in October. The crowning characteristics of the pellagra eruption were the symmetry and color. The wet form differed only in degree. When the dermatitis was severe, bullæ formed; when they broke large ulcers were left to mark their site, or large flakes of skin desquamated, leaving a raw surface. The whole clinical picture was analagous to a burn of the first degree. The wet form involved a greater area than the dry. This form had frequently been diagnosed as dermatitis exfoliativa. The buccal mucosa became very red, the tongue and mucosa of the lips showing particularly this characteristic symptom. The tongue, denuded of its epithelium, was smoth and glistening. Its color was cardinal red. Sandwith had called it the "bald tongue." The stomatitis was accompanied by a profuse flow of thick saliva. When the mouth was opened, strings of saliva would extend from the upper to the lower teeth. The small black or bluish-black papilla seen on the tongue had been given the name "stipple tongue" by Dr. Lavinder. The swollen and tender salivary glands, with the salivation and swollen gums, had often been mistaken for mercurial salivation, but there was absent that disgusting fetid odor so characteristic of the mercurial ptyalization. Other mucous membranes were inflamed. Hemorrhoids

were frequently complained of. The mucosa of the vagina was the seat of inflammation, and vulvovaginitis was not at all infrequent. Lombroso said that pyrosis was never absent. Vomiting sometimes occurred, but was not a constant feature. In advanced cases dysphagia was complained of. In some cases there were marked gastric symptoms. Diarrhea was a feature of the disease at some time in its course, and varied from a few soft stools a day to twenty or more. They were often as frequent at night as in the day. The diarrhea was obstinate and was not affected by the ordinary treatment of diet. It often improved when drugs were discontinued and the diet not restricted. It was due to disease of the spinal chord and involved the sympathetic system; it was a neuropathic manifestation. In the terminal stage, when rise of temperature set in, the diarrhea frequently ceased. Meteorism was present with the diarrhea. The diarrhea followed the same course as the erythema and stomatitis, namely, it had exacerbations and remissions and persisted through the spring and summer months, with a slight recrudescence in October, and then disappeared during winter to reappear the following spring. Pupillary abnormalities were striking in some localities, and in some seasons varying from year to year. The pupils reacted sluggishly, both in light and accommodation. The pupillary phenomena must be due to a disturbance in the cilio-spinal center. Pains in various portions of the body were often complained of. Tenderness at some point along the spine was almost constant. The mild cases were practically afebrile, with a morning temperature often subnormal. A temperature of from 102° to 108° F. or over was not infrequent in cases progressing to a fatal termination. The pulse increased with the toxemia or temperature, and counts of 160 were not unusual in fatal cases. There was nothing characteristic about the urine. The reflexes were usually exaggerated. Vertigo was complained of by nearly all the sufferers. Mental depression was as constant as the erythema and diarrhea and varied from a mild case of the blues to severe melancholia. Hallucinations and delusions were sure to occur at some time in the disease. While pellagrins were not talkative, at times they complained of real or imaginary ills. As the disease advanced they talked less, often not even answering questions, and finally they passed into a state of absolute mutism. The gait was either paralytic or paralytic spastic. The patients walked with their legs far apart, and as paresis set in the stride was very much decreased and the patient assumed a peculiar shuffling gait. Dr. Watson gave a lantern slide exhibition of cases after giving a very brief account of the pathology and treatment of the disease.

A Case of Pellagra.—Dr. Howard Fox presented a farmer, fifty-one years of age, a native of Georgia. The first symptoms of the disease began two years ago with loss of appetite and gradually increasing loss of flesh and strength. In the spring of 1908 an eruption appeared on the backs of the hands. His memory had gradually become very poor. Last summer he suffered from diarrhea and presented a fiery red tongue. Examination showed a dull, expressionless face, mental depression, a dermatitis of the backs of both hands, marked arteriosclerosis, some rigidity of the muscles of the legs, and exaggerated patellar reflexes. This was the first case of pellagra ever shown before any medical society in New York. Two cases had, however, been previously reported from Brooklyn by Dr. Sherwell, and one had recently been seen by Dr. Lavinder at the Marine Hospital on Staten Island.

SECTION ON OBSTETRICS AND GYNECOLOGY.

Stated Meeting, Held November 26, 1909.

Dr. John O. Polak in the Chair.

Large Lipoma of the Labium Majus Obstructing Labor.—Dr. Arnold Sturmdorf presented this tumor which was removed from a primipara, thirty-six years old. She claimed that she had carried this growth for eight years without discomfort. The tumor was quite hard, very slightly movable, and was attached by a broad base which involved and obliterated the outlines of the left labium majus. On its surface was a network of tortuous and dilated veins. It measured 12.5 cm. in length, 10.5 cm. in diameter, and 29.5 cm. in circumference. The fetal head was presenting at the vaginal outlet when she entered the hospital and was arrested by the projection of the growth on the left, and an old anchylosis of the right side. The removal of the growth permitted the prompt spontaneous delivery. This was one of the rarest of gynecological affections and represented a most unusual dystocia.

Adenocarcinoma of the Corpus Uteri.—Dr. Sturmdorf then presented this specimen. In addition to irregularity of outline and great increase in the number of glands, the epithelium proliferated, forming multiple irregular layers invading the corporeal structure of the uterus. The patient was a widow, fifty years old; she had had two children, eighteen and twenty years ago, with normal labors. The menopause occurred twelve years ago. She had a vaginal discharge which had existed for ten years, but she had never experienced any pain. On examination, the cervix appeared normal, but the uterus was somewhat enlarged and boggy, with adnexa free. An examination of the scrapings prompted a total hysterectomy. The pathologist reported this to be an adenocarcinoma of the uterus. This might assume a type sometimes spoken of as malignant adenoma, a glandular overgrowth in which the greatly increased glands invaded the musculature of the uterus. It was very difficult to differentiate such an early malignant adenoma from an advanced type of hyperplastic glandular endometritis, termed benign adenoma. The mucosa of the body of the uterus was entirely replaced by the cancer growth, which extended as far down as the internal os, and there stopped, leaving the cervical canal and vagina free from involvement.

Interstitial Ectopic Pregnancy and Tuboovarian Abscess in the Same Patient.—Dr. Sturmdorf also presented a uterus which showed an ectopic gestation on one side and a tuboovarian abscess on the other. This condition was not of rare occurrence. The patient was twenty-eight years old, married four years, and stated that she had never before been pregnant, and had never suffered from any gynecological affection. She had menstruated regularly seven weeks prior to her first examination; she admitted that when two weeks overdue, suspecting pregnancy, she had submitted to an attempt at artificial abortion; this resulted in producing an irregular, occasionally profuse, painless flow which had continued during the following four or five weeks. Her temperature was normal and there was no tenderness. Attached to the left side of the uterus was an irregularly shaped, soft, elastic mass which filled the left lower pelvis. The history, symptoms, and the mass seemed to make the diagnosis of ectopic pregnancy a logical one. Abdominal section, however, revealed the uterus to be completely embedded in extensive organized adhesions. The mass to the left which had been interpreted as the gestation proved to be an old tuboovarian abscess, while the junction of the opposite cornual area with the tubal isthmus presented the soft bulging of an existing ectopic gestation. Where they expected to find an ectopic, they found an abscess; where they expected nothing, they found the most dangerous form of ectopic pregnancy. The complete absence of all signs and symptoms pointing to the existing extensive results of previous infection were worthy of comment.

The Induction of Labor and Manual Dilatation of the Cervix by Harris's Method.—Dr. H. M. Little of Montreal read this paper. He said that during the past few months the tabulation of the statistics of some forty cases

of eclampsia and a compilation of the medical report of the Montreal Maternity Hospital for the past year had given him an opportunity to become familiar with certain features of the general work which had impressed him strongly. Two of these features which stood out strongly and seemed most worthy of attention were the results of the induction of labor, and those of *accouchement forcé* by the Harris's method. The reports of the Section on Obstetrics and Gynecology of the New York Academy of Medicine, always well written and attractively presented, were the most widely read of any American obstetric transactions, and served as a guide in the treatment to the majority of practising obstetricians in the United States. Records of 3,000 cases in Montreal showed an average of about 11 per cent. of contracted pelves. During the past year he found that with 87 contracted pelves there were 70 normal labors, and but 17 instances of dystocia. That was, 80 per cent. of the labors terminated without interference. If they considered that normal labors occurred in 80 per cent. of the 11 per cent. of all cases in which the pelvis was more or less contracted, it was a simple deduction to see that pelvic dystocia was to be expected in about one of fifty cases; and if they excluded from these, those in which forceps or version might be employed with advantage, the chances of serious pelvic dystocia were seen to be extremely remote. Owing to the success of certain advances along surgical lines, pubiotomy and the various modifications of abdominal section, they owed the favorable reception of two other operations, multiple incisions of the cervix and the so-called vaginal cesarean section. It was on account of the widespread notice that these two operations had obtained that he brought before the Section the results gained by two other and older operations which had fulfilled all purposes. He referred to the favorable results gained by the induction of labor and manual dilatation of the cervix. Dr. Little said he had been struck by the number of cases of dystocia on account of the birth of a child unusually large or exceedingly heavy, even though the pelvis was normal. Vaginal cesarean section had been recommended in cases where the cervix was rendered abnormal by carcinoma, fibroids, or extensive scars. It had also been suggested in cases of eclampsia, placenta prævia, heart disease, nepritis, chorea, vomiting of pregnancy, tuberculosis, and infrapartum infection. Labor had been induced 45 times in the series of 3,000 cases. The method employed was as follows: The vulva was first shaved and cleansed. The cervix was exposed and its anterior lip was fixed with a tenaculum. The bougie used was a moderate sized rectal tube, about 25 cm. long, in which holes, about 3/10 cm. in diameter, were made at intervals of about 5 cm. This was fixed upon a flexible metal director inserted about 5 cm. from its tip. The metal director served to hold the bougie steady during its passage into the cervix, and after director and bougie had passed into the cervix the director was steadied and the rubber tube shoved up between the membranes and the uterus by means of a long forceps. The director was then reinserted into the next opening in the tube, passed up until it was well within the cervix and the tube again shoved off up into the uterus. In this way it was possible to pass in the tube as if it were solid and yet allow the freest of excursion once it had gotten between the uterus and the membrane. The softness of the tube precluded the possibility of perforation of the uterus and the membranes were never ruptured. The average time from the introduction of the bougie till the onset of labor was six and a half hours. In spite of the early onset of pains in the majority of the cases, it was found necessary to interfere for the completion of labor in about one-half the cases. Nineteen of the 45 cases died, but as the operation was in by far the greater number of cases undertaken in the interest of the mother, this showing was relatively good, particularly when the deaths were analyzed. *Accouchement forcé,* or so-called "bloodless" dilatation of the cervix by Harris's method, had been employed on 52 occasions; two more cases were added where dilatation was accomplished by means of the Pomeroy bag. The indications were, eclampsia, 15 cases; to terminate labor after induction, 8; placenta prævia, 8; toxemia, to shorten labor, 4; danger to the mother or child during labor, 9; prolapse of the cord, 3; transverse presentation, 2; fever intrapartum, 2; extreme rigidity of the cervix, 1; other causes, 2; a total of 54 cases. There were five deaths, three cases of eclampsia, one case of placenta prævia, and one after pubiotomy. In the 52 cases operated on by the Harris's method but 14, or 29 per cent., escaped without a certain amount of laceration. In the two cases in which the Pomeroy bag was used there was more or less tearing of the cervix. Two dangers of manual dilatation, hemorrhage and infection, had not been noted to any extent. A total of 28 normal puerperiums in 49 cases, 57 per cent. was not unsatisfactory, particularly as seven of the eight moderately high temperatures after the use of Harris's method were noted, three times in association with placenta prævia, twice where they had high fever before the operation was undertaken, once in a case of pyelonephritis, and once after the placenta had been removed manually. In concluding, Dr. Little said that the induction of labor and occasionally the completion of labor by manual dilatation offered an alternative to surgical procedures in the treatment of many of the graver complications of labor. These two operations not only were simple but were capable of application under almost any circumstances; they were so simple that they might be employed by a practitioner even without the aid of assistants. When carefully employed they were practically devoid of danger and had the advantages of being not only of wide application but of almost universal use in that the manual dilatation of the cervix must be completely employed as a preliminary to either operation with forceps or version. Where carefully employed the maternal mortality should be nil, though particularly in the induction of labor there might occasionally be deaths from too long delay before labor was induced. The same, however, would apply no matter how the patient was delivered, for once the bougie was inserted it was but a short time until the patient either delivered herself spontaneously or could be delivered by other methods.

Dr. J. Clifton Edgar believed that if one had much experience in the use of Champetier's bags in the induction of premature labor, he would cling to this method; however, the method proposed by Dr. Little appealed to him, and he would try it. Whatever method was employed, the results depended upon the intrinsic irritability of the uterus. In some instances there would occur a very short labor; in others a very long one. It was the condition of the uterus itself that counted, and not so much the method employed. In the cardiac cases one should endeavor to shorten the second stage. With regard to *accouchement forcé,* he believed that all methods employed became after all a personal equation; they all had their use. Dr. Edgar obtained his best results with the use of the Pomeroy bag in *accouchement forcé;* but one could not rely upon the Pomeroy bag to open the uterus three and a half, or three and three-quarter inches within an hour, without lacerating the cervix. In obstetrical emergencies which demanded very rapid dilatation of the cervix, the choice of operation should depend upon the condition of the cervix. In New York one met with cervices that were very resistent, and it seemed to him that there should be no absolute choice of any one method. It was to be borne in mind at all times that it was the rigidity of the cervix that was to be overcome and which caused the danger.

Dr. James W. Markoe said that the old Krause catheter had been introduced into the uterus for the production of premature labor without the best results, and he believed

that with the new method with a rectal bougie better results would be obtained. During the past few years he had been in the habit of packing the cervix with iodoform gauze, packing it in well up, with the patient upon her back; he packed it in as tightly as he could. This had been a very serviceable method with him. However, this method with the rectal tube seemed to be of better service and induced labor quicker than with the small bougie. The induction of labor was not often carried out at the Lying-In Hospital; out of about 60,000 there had been but 256 patients on whom labor had been induced. This was a very small number, but they should remember that the cases came in late and this would account for the small number. With regard to *accouchement forcé*, where forcible dilatation of the uterus was required, in the hands of the inexperienced it was a very dangerous method and, therefore, should be done as little as possible. Among the 60,000 cases at the Lying-In Hospital, this operation had been performed but about 648 times. The cases calling for it were very varied. In one case, for instance, a woman had a cervix dilated to about two fingers and under her bed was a pool of blood. This was a case of central placenta prævia. The immediate delivery of the child called for a true *accouchement forcé*. When this was performed with the use of the bags, it was a slow process; his idea of the term *accouchement forcé* implied that it must be done rapidly. This operation was done in cases of placenta prævia, eclampsia, cases that demanded an immediate delivery of the child. At the Lying-In Hospital he usually used a steel dilator where the cervix was undilated before performing manual dilatation. The danger was not so much from the dilatation as it was in the extraction of the child through the rapidly dilated cervix. Dr. Markoe said he was delighted to hear the statistics from Montreal; he heartily agreed that too much surgical work was done and for the induction of labor, *accouchement forcé* should be more often employed, and would give better results when properly performed. It should, however, be done with great care. If improperly done there was great danger attached to its performance.

Dr. Charles Jewett said that the induction of labor by obstetric methods, properly carried out, was practically without maternal mortality. There were no fetal deaths that could be properly charged to the interruption of pregnancy when it could be done within the last two or three weeks. In contracted pelvis the operation, while it had not a large field, held an important place in obstetric surgery. There were four principal methods at their disposal: the Krause method, the hydrostatic bag, manual dilatation, and vaginal cesarean section. The choice must depend upon the individual case. In most cases the labor terminated within twenty-four hours. The inelastic water-bag was quicker than the bougie. Dr. Pomeroy with his bag had completed the dilatation in favorable cases within one hour. In many cases of placenta prævia this was the ideal method, especially in cases with hemorrhage with an undilated cervix. In the interest of asepsis it was better passed within the amniotic sac and it controlled the bleeding better. Manual dilatation was sometimes better than the bag or the bougie. Vaginal cesarean section found its chief indication in eclampsia with rigid cervix. This was especially true prior to the last one or two months, when extraction was easy. With reference to the technique in the use of the bougie, Dr. Jewett had not found it necessary to use an anesthetic. The patient was placed in the Sims position, the cervix exposed and drawn forward in the usual way. He used two bougies, the largest that could be had. Dr. Little's rectal tube would no doubt be a gain over the bougies usually employed. The knob was removed from the proximal end and a stilet introduced. The distal end was bent nearly at a right angle, making a large sweep about three or four inches from the end. This passed easily the angulation at the junction of the cervix and lower uterine segment. As the bougie entered the uterus, the stilet was withdrawn about one inch, and the soft nose of the bougie found its way between the membranes and the uterine wall without risk of harm. He did not remember having ruptured the membranes with this technique. The instrument was pushed up gently till resistance was felt, then the stilet was withdrawn and the rest of the bougie was fed into the uterus, inch by inch, catching it near the cervix with a Keith clamp. Most of the bougie he assumed was coiled up in the lower segment where it was most effective in provoking pains.

Dr. George L. Brodhead said that years ago, at the Sloane Maternity Hospital, the bougie was almost universally used for the induction of labor, but the membranes were ruptured so frequently that when the de Ribes bag was brought into use, he had tried it and had been using it ever since. Prolapse of the cord had happened in two or three instances, but the use of the bag had been, as a rule, a valuable and reliable method of procedure and so far as the maternal mortality was concerned, there was none. With regard to *accouchement forcé* he believed that prior to the operation, in cases of eclampsia, for instance, the use of the balloon was advisable in order to obtain both softening and dilatation, for the cervix in some of these cases was very rigid. In placenta prævia he was afraid to use *accouchement forcé*, preferring to use the Champetier bag until good dilatation of the cervix was obtained; then the foot should be brought down and the child extracted very slowly. Rupture of the uterus had occurred very frequently during the rapid dilatation of the cervix and subsequent extraction in placenta prævia, and he believed that generally speaking it would be safer to use the bag, or even to do version with slow extraction, than to resort to *accouchement forcé*.

Dr. Franklin A. Dorman said he had been very much interested and edified by Dr. Little's paper which showed so much thought. The induction of labor was indicated, even in a relatively large pelvis, when the woman was at term, when there was an excessively large child. The words in the paper sounded the keynote of the situation when the statement was made that these patients should not be allowed to go beyond a few days after term. At term the results were good in such cases. Many multiparæ, if advised to take a good dose of castor oil, or given a little digital stretching of the cervix, would go promptly into labor. This was a simple method of inducing labor. If the women were not at term, it was more difficult to bring on labor and get good results because of the poor muscular action. The labor would drag along and the women would often play out before the low uterine segment was dilated. Manually, one might then be unable to get the child out. In such cases one was occasionally justified in making a section of the lower segment of the uterus. In the cases of rigid cervices seen in eclampsia, the long and thick cervices, where one wished to get a softening of the cervices, it could be accomplished by the use of the bag better than by the use of the bougie; it produced a mechanical action not obtainable by the bougie. The bag certainly had an advantage over the bougie, although the uterus was more responsive to the latter. In cases of placenta prævia, one should not omit the use of the dilating bag. Such patients should be carefully watched. If one attempted to dilate the cervix manually, there was liable to occur a tear of the cervix. Dr. Dorman said he had seen many cases of ruptured uteri because the operators did not realize that they were tearing it.

Dr. Robert L. Dickinson said that two weeks before term, one could with advantage strip the membranes in most primiparæ, and even in multiparæ, and always when a large child was anticipated, and thus induce labor. They lost too many first children and mostly from over-develop-

ment. He felt very grateful to Dr. Little for introducing the use of the rectal tube. Dr. Dickinson had ruptured the membranes with Krause's bougie, and once had loosened the placental edge. The *x*-ray had taught them that any attempt, save by the proctoscope, to pass the rectal bougie well up into the colon would coil it in the rectum. The same thing would occur when it was passed into the uterus, and he did not believe it was as dangerous as the bougie. As to *accouchement forcé*, there was no method used to dilate the cervix but what brutally contused the parts, and left a thickened external os, not effaced, never taken up. He said he had taken a strong stand against the use of the Bozzi dilator. He preferred to use manual dilatation by Edgar's method when one feared to displace the engaged head. Pomeroy's bag had a field of usefulness in placenta prævia. Time was an important element in these cases. There was usually a rigid cervix in cases of eclampsia at the sixth or eighth month. He said he knew of no method so satisfactory in dealing with this ring of gristle as the cutting operation.

Dr. Asa Barnes Davis said that his experience with the use of the bougie in these cases showed that it was uncertain in its action. He had used, for a long time, packing with gauze to the exclusion of everything else. He packed well through the cervix as far as he possibly could, plugging the cervical canal and vagina as well. This he considered a very essential thing to do in inducing labor. His experience with the Pomeroy bags had been of a very limited nature. He had found that packing with gauze was very satisfactory and very efficient. They met with cases where it was necessary to empty the uterus rapidly; the element of time was a very important matter in some cases. In such cases one could not wait for the action of a bougie. Often dilatation was a very difficult thing. As a matter of fact, a large number of so-called dilatations were not dilatations at all. One could not dilate more than four fingers without tearing the cervix. As to the vaginal cesarean section, it was an easy matter to open the uterus by means of an incision; but it was a difficult matter to repair a cervix and uterus afterwards. Sometimes the tear extended in the direction of the incision; if it extended laterally one was apt to tear into large blood vessels when one would meet with an alarming hemorrhage.

State Medical Licensing Boards.

STATE BOARD EXAMINATION QUESTIONS.

Board of Medical Examiners of South Dakota.

July 14 *and* 15, 1909.

ANATOMY.

1. Give the fundamental principles of an animal cell. Describe briefly four classifications of cells.
2. What is cartilage? Name and describe the several kinds.
3. Define: Mulberry mass; primitive streak, ectoderm. What structures are formed from the mesoblastic layer?
4. Describe a complete uriniferous tubule, showing the blood supply and various kinds of epithelium.
5. Give origin and insertion: Psoas magnus: Serratus magnus; Teres major; Deltoid.
6. Give a description of the arteries and veins of the rectum.
7. Describe and trace the course of the lymphatics of the mammary gland.
8. What displacement occurs in an intracapsular fracture of the femur? Why?
9. Name and describe the ligaments of the knee joint.
10. Describe a hepatic lobule.

PHYSIOLOGY.

1. Where, in the human body, are the following substances found? (*a*) Fibrin; (*b*) mucin; (*c*) leucin; (*d*) chondrin.
2. Describe the nervous mechanism of muscular contraction.
3. Define stammering, and state the cause.
4. Describe the blood, and compare arterial with venous blood.
5. What is the physiologic function of the liver?
6. What is the rate of circulation of the blood in the (*a*) arteries, (*b*) veins, (*c*) capillaries?
7. Describe the physical properties of (*a*) lymph, and (*b*) chyle.
8. Define reflex nervous impulses, and give examples.
9. Explain the difference between human and cows' milk.
10. Define secretion, and name some of its products.

CHEMISTRY.

1. (*a*) What is chemistry? (*b*) What is meant by chemical force or affinity?
2. (*a*) Give a definition of a crystallized substance. (*b*) Under what condition will matter crystallize?
3. What is meant by the terms amorphous, polymorphous, isomorphous?
4. (*a*) Explain the term quantivalent. (*b*) Mention some univalent, bivalent, trivalent, and quadrivalent element.
5. If a certain volume of hydrogen weigh twenty grains, how much will a like volume of oxygen weigh?
6. State the difference between inspired and expired air, and explain how this is brought about.
7. Give chemical composition and general properties of bismuth subnitrate. Explain the dark color of the stools following its therapeutic use. Name its most dangerous impurity and give test for same.
8. (*a*) What substances might be indicated if a specimen of neutral or slightly acid urine show a precipitate upon boiling? (*b*) How would you differentiate between them?
9. (*a*) Give a test to detect sugar in the urine. (*b*) Give in detail a quantitative test for sugar in the urine.
10. State if the following prescription is chemically compatible. If not, why?

℞

Tinct. ferri chloridi, ʒvi.
Ext. buchu fl., ʒss.
Potassi citratis, ʒvi.
Aquæ dest. qs. ad, ʒiv.

M. et. Sig. Take a teaspoonful every four hours with a glass of water.

BACTERIOLOGY.

1. What is understood by ptomains? Toxins?
2. How do bacteria multiply?
3. When called to a case where diphtheria is suspected, describe fully the technique of taking a culture; the preferable culture medium and stain, and process of staining.
4. Name three conditions essential to bacterial growth. What are the most common microorganisms of suppuration?
5. What is the supposed microorganism of cerebrospinal meningitis? How is the bacteriological diagnosis of this disease made?

PATHOLOGY.

1. Contrast hyperemia and passive congestion
2. What is the pathology of arteriosclerosis?
3. Define osteomyelitis.
4. Give the technique of an examination of the sputum.
5. Give a brief outline of Ehrlich's side chain theory.
6. Describe "healing by second intention."
7. Give causes, symptoms, macroscopic, and microscopic findings in atrophic cirrhosis of the liver.
8. Define embolus, thrombus.
9. Give the pathology of urticaria.
10. Name three forms of nucleated red blood cell.

PRACTICE AND THERAPEUTICS.

1. What are the clinical forms of acute gastrointestinal catarrh of childhood?
2. What is varicella? Variola? Give differential diagnosis of same.
3. Define idiopathic anemia. Give symptoms. Differentiate idiopathic anemia and progressive pernicious anemia.
4. What is acute chorea? Give pathology, symptoms and treatment.
5. Describe neurosis of bladder. Give symptoms and treatment. In what way does neurosis of bladder differ from cystitis?
6. What is ascites? Give symptoms, physical signs, and treatment. What is liable to be mistaken for it?
7. Define bronchopneumonia. Lobar pneumonia. Give differential diagnosis.
8. (*a*) What are the modes of administering drugs? (*b*) Give therapeutic uses and contraindications of chloral hydrate.
9. Give symptoms of intestinal obstruction and name the different types.

10. Give therapeutic uses and contraindication of digitalis. Describe poisoning from digitalis.

OBSTETRICS.

1. Describe ovulation.
2. Describe a case of pregnancy at beginning of fourth month.
3. When would you apply the forceps? When would you not apply the forceps?
4. Give causes, symptoms, and dangers of a premature detachment of the placenta, and treatment.
5. Phlegmasia alba dolens. Give symptoms, treatment, and results.
6. What precautions do you take to prevent rupture of the perineum? If considerably torn, what do you do, when and how?
7. With right shoulder presenting, arm straight, and hand born, palm of the hand facing the right thigh of mother, thumb backward, what would be position of child in utero, and what would you do?
8. What is meant by the "stages of labor"?
9. How would you prevent mastitis?
10. Describe care of the mother for first three days after the birth.

DISEASES OF WOMEN.

1. Describe the contents of the female pelvic cavity, and show relations.
2. Give treatment in detail of a submucous fibroma.
3. Give the symptoms and treatment of a chronic retroversion of the uterus; (*a*) medical; (*b*) surgical, giving details of one operation.
4. Etiology and treatment of (*a*) cystocele; (*b*) rectocele.
5. Etiology, symptoms, and treatment of pelvic adhesions.

SURGERY.

1. Diagnose and treat a case of acute serous synovitis in its most frequent location.
2. Describe a case of cellulitis of the hand. Give treatment for same. What does it often accompany?
3. Give cause and treatment of varicose veins of the lower extremities.
4. Give the most common seat of fracture of the inferior maxillary, and its treatment.
5. Give cause and treatment for hallux valgus.
6. Describe Bassini's operation for the radical cure for inguinal hernia.
7. Diagnose a movable kidney. What operation would you perform for its relief? Describe the operation.
8. Diagnose an ischiorectal abscess. Give etiology and treatment.
9. Name the most common dislocation of the shoulder joint and give method of reduction.
10. Describe an operation for the radical cure of hydrocele.

EYE AND EAR.

1. (*a*) Give diagnosis of iritis. (*b*) Name, describe, and treat five common pathological conditions of the eye.
2. (*a*) Name all the bones which form the orbital cavity. (*b*) Which are common to both orbits?
3. What do you understand by the following: Hypopyon, Argyll-Robertson pupil, mydriasis, presbyopia, ptosis?
4. Where would you look for the cause of much of the ear trouble in children? Discuss briefly.
5. Describe and treat five pathological conditions of the ear.

JURISPRUDENCE.

1. Differentiate between antemortem and postmortem wounds.
2. What would guide you in determining whether a gunshot wound was self-inflicted?
3. Describe briefly duties of coroner when finding of dead body is reported to him.
4. What do you understand by abortion, infanticide, dementia, poison, syncope, catalepsy?
5. (*a*) Treat a case of opium poisoning. (*b*) Differentiate between poisoning from strychnine and arsenic.

ANSWERS TO STATE BOARD EXAMINATION QUESTIONS.

BOARD OF MEDICAL EXAMINERS OF SOUTH DAKOTA.

July 14 and 15, 1909.

ANATOMY.

1. *A typical cell* is the ultimate element of structure; it enters into the formation of all tissues. It consists of a tiny mass of protoplasm, and contains a nucleus and an attraction sphere, but as a rule no cell wall. Cells vary in shape and size (from about 1-3000 to 1-300 of an inch in diameter), and are characterized by power of movement, assimilation, growth, excretion, and reproduction. *Properties of cells:* (1) Irritability, or power of responding to a stimulus; (2) power of movement; (3) power of assimilation; (4) power of growth; (5) power of excretion, and (6) power of reproduction. Cells may be *classified* as: (1) Epithelial; (2) connective tissue; (3) muscle, and (4) nerve cells.

2. *Cartilage* is a form of connective tissue; it is firm and elastic; opaque, and of a bluish color. The varieties are: (1) *Hyaline*, in which the cells are relatively few and are imbedded in a quantity of ground substance. (2) *White fibrocartilage*, in which the ground substance contains bundles or layers of white fibers, between which are encapsulated cells. (3) *Yellow fibrocartilage*, in which the ground substance contains a network of yellow, elastic fibers, and the cartilage cells are in the meshes of this network.

3. *Mulberry mass* is the more or less globular mass of cells, the result of repeated segmentation of the fertilized ovum. *Primitive streak* is a linear marking appearing at the end of the germinal disc, and indicating the first trace of the embryo. *Ectoderm* is the outer layer of the blastoderm. From the *mesoblastic layer* are derived: The skeleton, connective tissues, muscles and bones, heart, blood-vessels, lymphatics, and spleen; the urinary and generative organs.

4. See Cunningham's "Anatomy" (1909), page 1139; or Gray's "Anatomy" (1908), page 1427.

5. PSOAS MAGNUS. *Origin:* Transverse processes of lumbar vertebræ; also from bodies of last thoracic and all lumbar vertebræ, with the intervertebral substance. *Insertion:* Lesser trochanter of femur. SERRATUS MAGNUS. *Origin:* Eight upper ribs and aponeurosis over intercostal muscles. *Insertion:* Vertebral border of costal surface of scapula. TERES MAJOR. *Origin:* Inferior angle of scapula and lower one-third of axillary border of scapula. *Insertion:* Inner edge of bicipital groove of humerus. DELTOID. *Origin:* From the outer third of anterior border and upper surface of the clavicle, from the outer margin and upper surface of the acromion process, and from the lower edge of the spine of the scapula. *Insertion:* Into the deltoid impression on the middle of the outer side of the shaft of the humerus.

6. *Arteries which supply the rectum:* (1) Superior hemorrhoidal (from inferior mesenteric); (2) middle hemorrhoidal (from internal iliac), and (3) inferior hemorrhoidal (from internal pudic). The veins correspond to the arteries, and commence in a plexus around the anus from this plexus vessels ascend between the muscular and mucous coat.

7. See Cunningham's "Anatomy" (1909), page 923; or Gray's "Anatomy" (1908), page 810.

8. In *intracapsular fracture of the femur:* (1) The lower fragment is drawn upward by the glutei, the rectus, the biceps, semimembranosus, and semitendinosus; (2) the limb is everted; this is due to the force of gravity (and external rotators).

9. *Ligaments of the knee-joint:* Anterior, or Ligamentum patellæ; posterior; internal lateral; two external laterals; capsular; external crucial; internal crucial; transverse; coronary; Ligamentum mucosum, and Ligamenta alaria. For a description of these ligaments, see Cunningham's "Anatomy" (1909), page 298; or Gray's "Anatomy" (1908), page 337.

10. A lobule of the liver is about 1-20 to 1-12 inch in diameter. It has a darkish red center and a lighter circumference. The center is occupied by an intralobular vein which collects the blood from the capillaries of the lobule, and flows into the sublobular vein, which latter opens into the hepatic vein. Around the lobules are the interlobular veins; these are branches of the portal system; capillaries passing from the circumference to the center of the lobule connect the interlobular and intralobular veins. Between the network of capillaries in the lobule the hepatic cells are packed.

PHYSIOLOGY.

1. (*a*) *Fibrin* is found in the blood and lymph; (*b*) *mucin*, in saliva and synovial fluid; (*c*) *leucin*, in the pancreas and spleen; (*d*) *chondrin*, in bone and cartilage.

2. The impulse causing ordinary muscular contractions originates in the centers of the brain or spinal cord, and then travels by the nerves going to the particular muscles. As such nerve enters a muscle it breaks up into a number of branches, which are distributed to all parts of the muscle. The terminal ends of the nerve are scattered in great numbers throughout the muscle, and the impulse

carried by the nerve is transmitted by the end plates to the various muscle fibers. Sometimes the muscular contraction may be reflex. (See below, Question 8.)

3. *Stammering* is defined as faltering and interrupted speech, especially hesitancy and interruption in speech from difficulty in enunciating certain letters properly. *Cause:* According to Kirkes, "stammering depends on a want of harmony between the action of the muscles (chiefly abdominal) which expel air through the larynx and that of the muscles which guard the orifice (rima glottidis) by which it escapes, and of those (of tongue, palate, etc.) which modulate the sound to the form of speech. Over either of these groups of muscles, by itself, a stammerer may have as much power as other people, but he cannot harmoniously arrange their conjoint actions."

4. The *blood* is fluid, somewhat viscid, red, specific gravity from 1055 to 1062, alkaline reaction, saltish taste, characteristic odor, variable temperature (average about 100° F.). The *constituents* are plasma and corpuscles. The *plasma* consists of water and solids (proteids, extractives, and inorganic salts). The *red corpuscles* consist of water and solids (hemoglobin, proteins, fat, and inorganic salts). The *white corpuscles* consist of water and solids (protein, leuconuclein, lecithin, histon, etc.). The *red cells* are biconcave discs, about 1-3200 of an inch in diameter; they are nonnucleated, and there are about 4,500,000 or 5,000,000 of them in each cubic millimeter of blood. They are elastic and soft, and their shape is changed by pressure, but is promptly regained on the removal of the pressure. Their color is yellowish. They contain hemoglobin. They carry oxygen from the lungs to the tissues. The white blood cells are spheroidal masses, varying in size, having no cell wall, and containing one or more nuclei; there are about 7,000 to 10,000 of them in each cubic millimeter of blood. They differ much in appearance, and are divided into (1) small mononuclear leucocytes, or lymphocytes; (2) large mononuclear; (3) transitional; (4) polynuclear, or polymorphonuclear, or neutrophile, and (5) eosinophile. They are all more or less granular, particularly the last two varieties named. They are probably formed in the spleen, lymphatic glands, and lymphoid tissues. Their fate is uncertain; it has been asserted that they are converted into red blood cells; they play a part in the formation of fibrin ferment; they are sometimes converted into pus cells. Their functions are (1) to serve as a protection to the body from the incursions of pathogenic microorganisms; (2) they take some part in the process of the coagulation of the blood; (3) they aid in the absorption of fats and peptones from the intestine, and (4) they help to maintain the proper proteid content of the blood plasma.

There are also *platelets*, which are very small, colorless, irregular shaped bodies; they are about one-fourth the diameter of a red corpuscle. Their function is not determined; it is possible that they take some part in the coagulation of the blood. In number they vary from about 200,000 to more than 500,000 in each cubic millimeter of blood. *Plasma* conveys nutriment to the tissue; it holds in solution the carbon dioxide and water which it receives from the tissues, and takes them to be eliminated by the lungs, kidneys, and skin; it also holds in solution urea and other nitrogenous substances that are taken to and excreted by the liver or kidneys. *Arterial blood* is bright red in color, contains more oxygen, less carbon dioxide, more water, and is slightly warmer; *venous blood* is purple in color, contains less oxygen, more carbon dioxide, less water, and is slightly cooler (except in the hepatic vein).

5. *The functions of the liver* are: (1) The secretion of bile; (2) the formation of glycogen; (3) the formation of urea and uric acid; (4) the manufacture of heat, and (5) the conversion of poisonous and harmful into inert material.

6. The rate of circulation in the *arteries* is about twelve inches in one second; in the *capillaries*, about one or two inches a minute; in the *veins*, about nine inches in a second.

7. *Lymph* is an albuminous, straw-colored fluid, containing lymph corpuscles; it is alkaline in reaction, has a specific gravity of about 1015, has a salty taste, and no odor; it clots in the same manner as blood. *Chyle* is much the same, but contains fat; it is opaque and whitish.

8. *Reflex actions* are involuntary or unconscious movements, due to suitable stimuli. They depend upon the integrity of the *reflex arc*, which is a complex made up of: (1) A surface capable of receiving an impression; (2) an afferent nerve; (3) a nerve cell capable of receiving and also of sending out impulses; (4) an efferent nerve, and (5) a surface capable of responding in some way to the impulse conveyed by the efferent nerve. Reflexes are classified as: (1) Superficial, (2) deep, and (3) visceral. *Example:* The patellar reflex consists of a contraction of the extensor muscles of the leg and a movement of the foot forward when the Ligamentum patellæ is struck; the quadriceps extensor must first be slightly stretched by putting one knee over the other. Its integrity depends upon a healthy condition of the entire reflex arc, consisting of tendon, afferent or sensory nerve, posterior roots, and anterior horn of the spinal cord, the efferent or motor nerve, and the muscle itself.

9. Human milk contains less proteids and fats and salts then cow's milk, and at the same time contains more sugar and more water.

10. *Secretion* means the process by which some of the constituents of the blood are separated from the blood stream (by the activities of the capillary endothelium, as the blood passes through the capillaries) and elaborated into other material. The products of secretion vary with the gland or membrane where it occurs. Thus: Saliva, tears, milk, bile, gastric juice, synovial fluid, serous fluid, pancreatic juice.

CHEMISTRY.

1. (*a*) *Chemistry* is that branch of science which treats of the composition of bodies, their changes in composition, and the laws governing such changes. (*b*) *Chemical affinity* is the force that binds atoms together to form molecules.

2. (*a*) *Crystalline substances* are solid bodies of a definite geometrical shape, which conduct heat more readily in some directions than in others; when broken, separate in certain directions (called planes of cleavage) more readily than in others, and modify the course of light according to the direction in which the rays pass through it. (*b*) *Conditions under which matter will crystallize:* There must be the possibility of the freest motion of the smallest particles of the matter to be crystallized; hence the substances must be heated (melted) or dissolved in some suitable agent, or must be in the gaseous state. Some substances will never crystallize.

3. An *amorphous* substance is one that is not crystalline. A *polymorphous* substance is one that can crystallize in more than one system. *Isomorphous* substances are different substances which will crystallize in forms identical with each other.

4. (*a*) *Quantivalence* is the combining power of an element or radicle expressed in terms of the number of hydrogen atoms it can unite with or replace. (*b*) *Univalent:* Hydrogen, chlorin, bromin, iodin, sodium, potassium, silver. *Bivalent:* Oxygen, sulphur, calcium, barium, lead, mercury. *Trivalent:* Nitrogen, phosphorus, arsenic, antimony, boron, bismuth. *Quadrivalent:* Carbon, silicon, tin, platinum.

5. If a certain volume of hydrogen weigh twenty grains, a like volume of oxygen will weigh sixteen times as much, namely, three hundred and twenty grains.

6.

	INSPIRED AIR	EXPIRED AIR
Oxygen	21 per cent.	16.6 per cent.
Nitrogen	79 per cent.	79 per cent.
Carbon dioxide...	0.04 per cent.	4.4 per cent.
Other gases.....	Rare.	Often present.
Watery vapor.....	Variable.	Saturated.
Temperature	Variable.	That of body.
Volume	Varies.	Diminished.
Bacteria	Always present.	None.
Dust	Always present.	None.

In inspiration, oxygen is taken in; it then combines with the hemoglobin of the blood, and is carried round to the tissues. The carbon dioxide is given off in the tissues to the plasma of the blood, by which it is carried round to the lungs and given off in expiration.

7. *Bismuth subnitrate* has the chemical composition $BiONO_3$. It is a heavy, white powder, odorless, almost tasteless, slightly acid in reaction; it is decomposed by pure water. They blacken the stools by forming bismuth sulphide with the hydrogen sulphide of the intestine. Its most dangerous impurity is arsenic. This may be detected by the Reinisch test, which is conducted as follows: Make a solution of the bismuth subnitrate, then add a little pure HCl; suspend in the fluid a small strip of bright copper foil, and boil. If a deposit forms on the copper, remove the copper, wash it with pure water, dry on filter paper, but be careful not to rub off the deposit. Coil up the copper and put it into a clean, dry glass tube, open at both ends, and apply heat at the part where the copper is. If arsenic is present there will appear in the cold part of the tube a mirror, which will be found on microscopical examination to consist of octahedral crystals of arsenic trioxide.

8. (*a*) Phosphates and albumin. (*b*) Add a little nitric acid; this will dissolve the phosphates, but will not affect the albumin.

9. (*a*) *Fermentation test:* Three Smith's fermentation tubes are used, each containing a little compressed yeast, one filled with the liquid to be tested, the second with pure water, and the third with a dilute solution of glucose, and the three are put in a warm place over night. If gas collects in the first and third tubes, but not in the second, the liquid contains sugar; if gas collects in the third only it does not; under any other circumstances the yeast is at fault.

(*b*) *Fehling's method for the quantitative estimation:* The solution is made as follows: (1) Dissolve cupric sulphate 51.98 gm., in water to 500.00 c.c.; (2) dissolve Rochelle salt, 259.0 gm., in sodium hydroxide soln. sp. gr. 1.12 to 1000 c.c. When required for use, one volume of 1 is to be mixed with two volumes of 2. The copper contained in 10 c.c. of this mixture is precipitated completely, as cuprous oxide, by 0.05 gm. of glucose. "To determine the quantity of sugar, place 10 c.c. of the mixed soln. in a flask of about 250 c.c. capacity; dilute with H_2O to about 30 c.c., and heat to boiling. On the other hand, the urine to be tested is diluted and thoroughly mixed with four volumes of H_2O if it be poor in sugar, or with nine volumes of H_2O if highly saccharine, and a burette filled with the mixture. When the Fehling soln. boils, add a few gtt. NH_4HO and then 5 c.c. of the urine from the burette, boil again, and continue the alternate addition of diluted urine and boiling of the mixture until the blue color is quite faint. Now add the diluted urine in quantities of 1 c.c. at a time, boiling after each addition until the blue color just disappears. Have ready a small filter, and, having filtered through it a few gtt. of the hot mixture, acidulate the filtrate with acetic acid and add to it 1 gtt. soln. of potassium ferrocyanide. If a brownish tinge be produced, add another ½ c.c. of dil. urine to the flask, boil, and test with ferrocyanide as before. Continue this proceeding until no brown tinge is produced. The burette reading, taken at this point, gives the number of c.c. of dilute urine containing 0.05 gm. glucose, and this divided by 5 or 10, according as the urine was diluted with 4 or 9 volumes of H_2O, gives the number of c.c. of urine containing 0.05 gm. sugar. The number of c.c. urine passed in twenty-four hours divided by twenty times the number of c.c. containing 0.5 gm. glucose gives the elimination of glucose in twenty-four hours in grams.

10. The prescription is incompatible. The water will cause the fluid extract to throw down a precipitate.

BACTERIOLOGY.

1. *Ptomains* are the putrefaction products of dead animal tissues or fluids. *Toxins* are the poisonous products of pathogenic bacteria.

2. Bacteria multiply by fission. A bacterium about to divide seems to be larger than normal, and if it is a coccus it becomes more ovoid; changes occur first in the nucleus, and the bacterium just falls in two. Cocci may divide in one, two, or three directions of space; bacilli divide transversely to their long axis, and spirilla divide transversely to their long diameter.

3. A sterile swab is rubbed over any visible membrane on the tonsils or throat, and is then immediately passed over the surface of the serum in a culture tube. The tube of culture, thus inoculated, is placed in an incubator at 37° C. for about twelve hours, when it is ready for examination. A sterile platinum wire is inserted into the culture tube, and a number of colonies of a whitish color are removed by it and placed on a clean cover slip and smeared over its surface. The smear is allowed to dry, is passed two or three times through a flame to fix the bacteria, and is then covered for about five or six minutes with a Loeffler's methylene-blue solution. The cover slip is then rinsed in clean water, dried, and mounted. The bacilli of diphtheria appear as short, thick rods with rounded ends; irregular forms are characteristic of this bacillus, and the staining will appear pronounced in some parts of the bacilli and deficient in other parts. *Methods of culture:* The bacillus of diphtheria grows upon all the ordinary culture media, and can be readily obtained in pure culture. Loeffler's blood serum, particularly with the addition of a little glucose, is an admirable medium for the rapid growth of this bacillus. The medium should be alkaline and not less than 20° C. *Method of staining:* It stains with any aqueous solution of an anilin dye, and quite characteristically with Loeffler's alkaline methylene blue. Neisser's stain is also recognized. The bacilli also stain well by Gram's method.

4. Three conditions essential to bacterial growth: Rest, moisture, neutral or feebly alkaline reaction. *The most common microorganisms of suppuration* are: *Staphylococcus pyogenes aureus, Staphylococcus pyogenes albus, Staphylococcus pyogenes citreus, Streptococcus pyogenes.*

5. The supposed microorganism of cerebrospinal meningitis is the *Diplococcus intracellularis meningitidis.* Lumbar puncture is performed, and about 10 c.c. of the cerebrospinal fluid is withdrawn. About 1 c.c. of this is dropped into sterile test tubes. It is cultivated on agar plates or Loeffler's blood serum mixture, and recoognized with the microscope.

PATHOLOGY.

1. *Active hyperemia* means that there is an excess of arterial blood in a part, and is generally accompanied by an increase in the rate of blood flow. In *passive congestion* there is still an excess of blood, but it is in the veins and capillaries, and the blood flow is retarded.

2. In *arteriosclerosis* it is mainly the innner coat which is affected; this becomes thickened by layers of fibrous tissue owing to the proliferation of the subendothelial connective tissue cells. This thickening is not uniform. The elastic layer becomes granular, and it may be partially destroyed. Where high arterial tension exists the media is affected, and the muscle fibers become hypertrophied; sometimes degeneration occurs here. The vessels increase in length and thickness, becoming tortuous; they also feel resistant and cord-like.

3. *Osteomyelitis* is inflammation of bone and marrow.

4. As the sputum is generally examined for tubercle bacilli, that will be described. The sputum must be recent, free from particles of food or other foreign matter; select a cheesy-looking nodule and smear it on a slide, making the smear as thin as possible. Then cover it with some carbol-fuchsin and let it steam over a small flame for about two minutes, care being taken that it does not boil. Wash it thoroughly in water and then decolorize by immersing it in a solution of any dilute mineral acid for about a minute. Then make a contrast stain with solution of Loeffler's methylene blue for about a minute; wash it again and examine with oil immersion lens. The tubercle bacilli will appear as thin red rods, while all other bacteria will appear blue.

5. "*Ehrlich's side chain theory of immunity* is based on the idea that the toxin destroys a cell by entering into chemical union with it. The molecule of toxin contains at least two groups of atoms, a *toxophore* group, in which the poisonous principle resides, and a *haptophore* group, which brings the toxophore group into touch with the cell and through which chemical combination takes place. Similarly, the cell contains a haptophore group, but the toxophore group of the toxin can only unite with it and destroy it when its haptophore companion has affinity with that of the cell. If that affinity does not exist, the two haptophore groups do not unite, the toxophore group does not come into contact with the cell, and the animal is immune. Such is natural immunity. If there is affinity and the cell can throw off a haptophore group (antitoxin), which in its detached condition unites with the haptophore group of the toxin, the toxophore group has then nothing with which it can unite and the animal is immunized. When the individual has to contend with a bacterium as well as its toxin, the same principle obtains. Immunity is established by the production of a double haptophore group, one for the bacterium, the other for its toxin."—(Stenhouse's *Pathology.*)

6. *Healing by second intention or granulation* occurs when the edges of the wound have not been brought together. "Exudation of plasma and leucocytes occurs, followed by fibroblasts and budding from the capillaries, thus forming granulation tissue. The dead tissues or sloughs are separated, and a red area of granulation is then exposed. The deeper layer of granulation tissue is converted into fibrocicatricial tissue, which contracts, and so the wound gradually lessens in size. In the meantime epithelium spreads in from the edge over the surface, and so the scar is completed."—(*Aids to Surgery.*)

7. *Atrophic cirrhosis of the liver is caused by:* Poisons, alcohol, fatty acids, specific fevers, microorganisms absorbed from the intestine, and syphilis. *Symptoms:* Dyspepsia, furred tongue, high colored urine, hematemesis, ascites. *Pathology:* The liver is shrunken and indurated, rough, and of a pale or yellow color; a growth of new connective tissue is disposed in broad bands which run in various directions, and by their contraction divide the liver into numerous irregular lobes. Many acini may be affected at one time. The capsule may be thickened, or adherent to the diaphragm. Jaundice is slight, and comes on late; ascites is pronounced and may occur early.

8. An *embolus* is a body which plugs up a blood-vessel, and is carried there from some other part of the circulation. A *thrombus* is a clot in a blood-vessel during life.

9. In *urticaria* the wheal is produced by some disturbance to the vasomotor nervous apparatus. It is circumscribed, and consists of an edema of the epidermis. There may be dilatation of the cutaneous vessels, with exudation of serum and white blood cells. This exudation may cause a pressure anemia, which produces the white appearance of the skin; around this is a red areola, due to the engagement of the peripheral vessels.

10. (1) *Normoblast,* same size as normal red blood cell; (2) *microblast,* which is smaller; (3) *megaloblast,* which is larger than the normal red cell.

PRACTICE AND THERAPEUTICS.

1. (1) Simple, and (2) cholera infantum.

2. *Varicella* is chickenpox; *variola* is smallpox. (1) Very young children are attacked with varicella, whereas variola usually shows itself in adults. (2) Vaccinated children readily take varicella; not so variola, even in the modified form. (3) Children who have had varicella may contract variola, even soon afterward; or the two diseases may co-exist. (4) Varicella is not inoculable, whereas variola is notoriously so. (5) The eruption of varicella appears in twenty-four hours; that of variola not till the third day. (6) The febrile symptoms continue after the eruption appears in varicella; those of variola subside. (7) In varicella the spots come out in successive crops; this is never seen in variola. (8) The spots in varicella are unilocular, and collapse on being punctured; the spots in variola are multilocular, and do not collapse on being punctured. (9) In varicella the eruption is very irregular, and appears over the body generally; in variola it appears in groups of threes and fives, and is always seen on the limbs. (10) The papule in varicella is soft, and disappears on stretching the skin; in variola it is hard and shotty, and does not disappear on stretching the skin.

3. See French's "Practice of Medicine" (1907), pages 508 and 510; or Osler's "Practice of Medicine" (1909), pages 724 and 726. Idiopathic anemia and progressive pernicious anemia are one and the same disease.

4. See French's "Practice of Medicine" (1907), page 1117; or Osler's "Practice of Medicine" (1909), page 1045.

5. Neurosis of the bladder is the name which includes a number of conditions, such as: Hyperesthesia, neuralgia, atony, paralysis, and hysteria of the bladder; also incontinence of urine. Cystitis is inflammation of the bladder. See Rose and Carlers' "Surgery" (1908), pages 1192, 1201; or De Costa's "Surgery" (1908), pages 1130, 1135.

6. ASCITES. *Symptoms, etc.:* Generally of gradual onset; abdominal distention, sense of weight and fulness; dyspnea; gastrointestinal disturbances; lineæ albicantes, presence of fluid may be detected by palpation, percussion or aspiration. If due to heart or lung disease, ascites will occur elsewhere, and the legs are generally affected first; in hepatic disorders the abdominal distention is marked and appears early; in renal disease, the abdominal fluid is generally small in amount. *Treatment:* Tapping, drainage, incision, and administration of cathartics have all been recommended. Ovarian tumor, pregnancy, distended bladder, pancreatic cyst, and echinococcus cyst may be mistaken for it.

7. *Bronchopneumonia* is an acute inflammation of the terminal bronchi, air cells, and interstitial tissue of isolated lobules of the lungs, or groups of globules. *Lobar pneumonia* is an acute infectious disease of the lungs, with inflammation and consolidation of one or more lobes of the lung.

LOBAR PNEUMONIA	BRONCHOPNEUMONIA
Generally a primary disease.	Generally secondary (to bronchitis or an infectious disease).
Age has little influence.	Generally found in very young or very old.
Sudden onset.	Gradual onset.
Fever is high and regular.	Fever is not so high, and is irregular.
Ends by crisis between sixth and tenth day.	Ends by lysis, at no particular date.
Generally only one lung affected.	Generally both lungs affected.
The physical signs are distinct, and there is a large area of consolidation.	Physical signs indistinct, and the evidences of consolidation are indefinite.
Sputum is rusty.	Sputum is rather streaked with blood.

8. (*a*) By mouth, inhalation, skin, rectum, vagina, hypodermic, and in veins. (*b*) Chloral hydrate is used as an antiseptic, counterirritant, hypnotic, and to alleviate whooping cough, tetanus, and strychnine poisoning. It is contraindicated in diseases of heart, lungs, stomach, and bowels.

9.

STRANGULATION.	INTUSSUSCEPTION.	TWISTS (VOLVULUS).
Subjective Symptoms.	*Subjective Symptoms.*	*Subjective Symptoms.*
1. Generally occurs after age of 20.	1. Most frequent in childhood.	1. Most frequent after age of 30.
2. Pain localized, rapid collapse.	2. Constant tenesmus.	2. Pain diffuse.
3. Pain intense, paroxysmal in character.	3. Pain develops suddenly and is continuous.	3. Pain paroxysmal; recurs less often than in strangulation.
4. Constipation complete.	4. Frequent diarrhea, passage of bloody mucus.	4. Constipation complete.
Objective Symptoms.	*Objective Symptoms.*	*Objective Symptoms.*
1. Temperature often subnormal.	1. Temperature normal or subnormal.	1. Temperature slightly elevated.
2. Pulse very weak.	2. Same as in strangulation.	2. Same as in strangulation.
3. Stercoraceous vomiting comes on early.	3. Same as in strangulation.	3. Same as in strangulation.
4. Location in small intestine.	4. Localization in small intestine; bowel frequently protrudes at rectum.	4. Location, small intestine; abdomen often protrudes, in certain areas, giving dullness on percussion.

10. Digitalis is indicated in diseases of the heart: (1) when the heart action is rapid and feeble, with low arterial tension; (2) in mitral lesions when compensation has begun to fail; (3) in nonvalvular cardiac affections; (4) in irritable heart, due to nerve exhaustion. Digitalis is contraindicated in diseases of the heart: (1) in aortic lesions when uncombined with mitral lesions; (2) when the heart action is strong, and arterial tension high. Digitalis is also a diuretic; and it is also used in some forms of nephritis, exophthalmic goiter, pneumonia, chronic bronchitis, etc. In *poisoning* there are: Nausea and vomiting, sometimes colic and diarrhea, slow pulse, dyspnea, cold extremities, headache, vertigo, somnolence, and syncope; death may occur.

OBSTETRICS.

1. See Williams' "Obstetrics" (1909), page 83; or Hirst's "Obstetrics" (1909), page 61.

2. See Williams' "Obstetrics" (1909), pages 180 and 190; or Hirst's "Obstetrics" (1909), pages 189 and 204.

3. *Indications for the use of forceps* are: (1) *Forces at fault:* Inertia uteri in the presence of conditions likely to jeopardize the interests of mother or child. (*a*) Impending exhaustion; (*b*) arrest of head, from feeble pains. (2) *Passages at fault:* Moderate narrowing, 3¼ to 3¾ inches, true conjugate; moderate obstruction in the soft parts. (3) *Passenger at fault:* A. Dystocia due to (*a*) occipito-posterior; (*b*) mentoanterior face; (*c*) breech arrested in cavity. B. Evidence of fetal exhaustion (pulse above 160 or below 100 per minute). (4) *Accidental complications:* Hemorrhage; prolapse funis; eclampsia. All acute or chronic diseases or complications in which immediate delivery is required in the interest of mother or child, or both. *Contraindications:* Mechanical obstruction in the parturient canal; incomplete dilatation of the os; nonrupture of membranes; non-engagement of the presenting part; the fetal head being too large or too small; distended bladder or rectum.

4. See Williams' "Obstetrics" (1909), pages 289 and 805; or Hirst's "Obstetrics" (1909), page 583.

5. See Williams' "Obstetrics" (1909), pages 865 and 898; or Hirst's "Obstetrics" (1909), page 761.

6. See Williams' "Obstetrics" (1909), pages 316, 317, and 325; or Hirst's "Obstetrics" (1909), pages 333 and 607.

7. Position is L.Scap.A. The head of the fetus is in the left iliac fossa, back anterior, extremities, on right side in upper part of abdomen. Do not replace the arm; version: if impaction is present, decapitation or cesarean section.

8. See Williams' "Obstetrics" (1909), page 226; or Hirst's "Obstetrics" (1909), page 320.

9. See Williams' "Obstetrics" (1909), page 914; or Hirst's "Obstetrics" (1909), page 708.
10. See Williams' "Obstetrics" (1909), page 340; or Hirst's "Obstetrics" (1909), page 364.

DISEASES OF WOMEN.

1. See Gray's "Anatomy" (1908), pages 1440 and 1495.
2. It may become polypoid, and project from the os uteri; it should then be removed, and if possible the pedicle should be first twisted. If large, the fibroid may have to be removed piecemeal, and the hemorrhage can be stopped by pressure and packing, or by a clamp forceps. If the tumor is entirely within the uterine cavity, the cervix must be dilated and the fibroid then removed, care being taken not to perforate the wall of the uterus. The patient should be in the lithotomy position, and proper antiseptic and aseptic precautions must be observed.
3. *Symptoms:* Pain, or a feeling of weight and fullness in the pelvis, constipation or discomfort during defecation, tubes and ovaries are dragged upon and the latter may be prolapsed, dyspareunia, dysmenorrhea, possibly sterility, metrorrhagia, leucorrhea, and reflex disturbances. *Treatment:* (*a*) Replace the uterus with fingers, or sound; keep it in place with pessary or tampons (adhesions if present must have been broken up); (*b*) shorten round ligament, or perform hysteropexy. See Rose and Carless' "Surgery" (1908), page 1278.
4. *Etiology:* Relaxation of vaginal walls; generally due to partruition, and torn perineum; lax uterine supports; subinvolution of uterus; prolapse of uterus. *Treatment:* Mend perineum, replace uterus, shorten round ligament if latter are too lax, colponhaphy.

SURGERY.

1. The knee is the joint most frequently affected. See Rose and Carless' "Surgery" (1908), page 642; or Da Costa's "Surgery" (1908), page 546.
2. See Rose and Carless' "Surgery" (1908), page 76; or Da Costa's "Surgery" (1908), page 203. It often accompanies a wound or abrasion.
3. See Rose and Carless' "Surgery" (1908), page 350; or Da Costa's "Surgery" (1908), page 351.
4. See Rose and Carless' "Surgery" (1908), page 448; or Da Costa's "Surgery" (1908), page 472.
5. See Rose and Carless' "Surgery" (1908), page 461; or Da Costa's "Surgery" (1908), page 664.
6. See Rose and Carless' "Surgery" (1908), page 1081; or Da Costa's "Surgery" (1908), page 978.
7. See Rose and Carless' "Surgery" (1908), page 1159; or Da Costa's "Surgery" (1908), page 1101.
8. See Rose and Carless' "Surgery" (1908), page 1132; or Da Costa's "Surgery" (1908), page 1008.
9. The subcoracoid is the most common. See Rose and Carless' "Surgery" (1908), page 622; or Da Costa's "Surgery" (1908), page 590.
10. See Rose and Carless' "Surgery" (1908), page 1267; or Da Costa's "Surgery" (1908), page 1202.

EYE AND EAR.

1. (*a*)

ACUTE IRITIS.	ACUTE CONJUNCTIVITIS.	ACUTE GLAUCOMA.
1. Pupil: small, sluggish, irregular after atropine.	Normal.	Dilated, oval, fixed.
2. Iris: swollen, dirty, lymph on surface.	Clean and bright.	Swollen and discolored.
3. Anterior chamber: normal (or deeper, with turbid contents).	Normal.	Shallow.
4. Cornea: clear (or with deposits on back).	Clear.	Steamy; *anesthetic.*
5. Ciliary region: injected.	Not injected.	Injected.
6. Conjunctiva: usually some injection.	Red, opaque, perhaps swollen.	Great congestion, perhaps chemosis.
7. Discharge: tears only.	Muco-pus.	Tears only.
8. Palpation: tension normal (occasionally + 1); tender in ciliary region.	Tension normal, not tender.	Tension + 2 to 3, very tender.
9. Pain: over forehead and nose, worse at night.	Sand or grit in eyes.	Intense neuralgia in and about eyes, nausea, vomiting.
10. Vision: clouded.	Scarcely affected.	Rapidly lost; field extremely limited; "rainbow rings" seen.
11. Disc: if seen, normal.	Normal.	If seen, cupped, and arterial pulsation.

(*b*) (1) *Trachoma* is a chronic disease of the conjunctiva, marked by granulation of the eyelids, later by atrophy, and cicatricial contraction. *Treatment:* Astringents, expression, or excision. (2) *Glaucoma* a condition characterized by increased ocular tension, dilatation of pupil, diminution of sight, and atrophy of the optic disc. *Treatment:* Iridectomy. (3) *Ophthalmia neonatorum* is an infectious, purulent inflammation of the conjunctiva in the newborn, due to the gonococcus or other pyogenic germ; produced by contact of the eye with the vaginal secretion of the mother during labor, or infected fingers, or instruments, etc. *Treatment:* Wash the eyes carefully every half hour with a saturated solution of boric acid; pus must not be allowed to accumulate. Two drops of a 2 per cent. solution of nitrate of silver must also be dropped on to the cornea every night and morning. The eyes must be covered with a light, cold, wet compress. The patient must be isolated, and all cloths and compresses used must be burnt. (4) and (5) *Iritis* and *Conjunctivitis:* See above, Q. 1 (*a*). *Treatment of iritis* is causal, abstraction of blood from temples, atropine, diaphoresis, shielding the eye from light. *Treatment of conjunctivitis:* If there is much swelling and scanty secretion, compresses (iced or hot), instillation of boric acid or bichloride solution; in profuse secretion with relaxed conjunctiva, silver nitrate solution; in phlyctenular conjunctivitis, calomel or ointment of yellow oxide of mercury; or alum or tannic acid solutions.
2. (*a*) Frontal, ethmoid, sphenoid, lachrymal, malar, palate, superior maxillary. (*b*) Frontal ethmoid, sphenoid.
3. *Hypopyon* is a collection of pus in the bottom of the anterior chamber of the eye. *Argyll-Robertson pupil* is a condition in which the pupil accommodates for distance but not for light. *Mydriasis* is dilatation of the pupil. *Presbyopia* is loss of accommodative power of the eye, occurring normally in advanced life. *Ptosis* is drooping of the upper eyelid.
4. In the nasopharynx. Adenoids may be the cause; they may cause deafness, they may occlude the Eustachian tube, or excite a catarrhal inflammation which may spread through the tube to the ear, or infection may spread by the same route, causing otitis or other troubles.
5. (1) *Impacted cerumen.* Disintegrate it with hydrogen peroxide, which is left in the ear a few minutes, and followed by an irrigation of warm water. (2) *Furuncle.* Hot applications; cleansing with hydrogen peroxide; morphine, and calcium sulphide internally; incision. (3) *Foreign bodies:* First see that there is a foreign body. Insects may be removed by warm water or chloroform oil. Careful syringing may remove other bodies. (4) *Rupture of membrane* from explosion of guns, or sudden condensation of air: Rest, cleanse the meatus, gentle irrigation with warm bichloride solution (1:10 000). (5) *Stricture of Eustachian tube:* Application of bougie, and inflation with superheated air may promote absorption of the new tissue.

JURISPRUDENCE.

1. *Ante-mortem* wounds generally show hemorrhage, coagulated blood, eversion of the edges and retraction of the sides; pus, gangrene, or beginning cicatrization also indicate that the wound was inflicted during life. *Post-mortem wounds*, the reverse of all this.
2. The location of the wound, the presence or absence of weapons, character of wound, the burning or charring of skin or clothing.
3. If cause of death is unknown or suspicious (possibility of either homicide, or suicide, or other crime), it is the duty to discover the *cause of death* (it is no part of his business to discover the individual who caused it). He

calls a jury to view the body and establish its identity; an inquest is held, witnesses are examined, possibly an autopsy is performed, and the jury renders a verdict.

4. *Abortion* is expulsion of the fetus before the term of gestation is complete. *Infanticide* is destruction of life of a newborn child. *Dementia* is a condition of mental enfeeblement, gradually progressing to mental decay. *Poison* is a substance which on being in solution in the blood will cause death or serious bodily harm. *Syncope* is suspended animation, due to sudden failure of the action of the heart. *Catalepsy* is a condition in which there is abolition of sensation and motion, with rigidity of muscles and slow pulse.

5. For *opium poisoning:* Wash into the stomach with a dilute solution of potassium permanganate, leaving about 500 c.c. in the stomach. Maintain respiration. Keep the patient moving. Strong coffee may be given. The urine should be drawn off by catheter. In *poisoning by strychnine:* Sense of suffocation, twitchings of muscles, followed by tetanic convulsions and opisthonotos. Mental faculties unaffected, face congested and anxious; eyes staring, lips livid; much thirst. In *poisoning by arsenic:* Faintness, nausea, incessant vomiting, epigastric pain, headache, diarrhea, tightness and heat of throat and fauces, thirst, catching in the breath, restlessness, debility, cramp in the legs, and convulsive twitchings. The skin becomes cold and clammy. In some cases the symptoms are those of collapse, with but little pain, vomiting, or diarrhea.

BULLETIN OF APPROACHING EXAMINATIONS.†

STATE	NAME AND ADDRESS OF SECRETARY	PLACE AND DATE OF NEXT EXAMINATION	
Alabama*	W. H. Sanders, Montgomery	Montgomery	June —
Arizona*	Ancil Martin, Phoenix	Phoenix	April 4
Arkansas	F. T. Murphy, Brinkley	Little Rock	May 10
California*	Chas. L. Tisdale, 1879 Sutter Street, San Francisco	San Francisco	April 5
Colorado	S. D. Van Meter, 1723 Tremont Street, Denver	Denver	April 5
Connecticut*	Chas. A. Tuttle, New Haven	New Haven	Mar. 8
Delaware	J. H. Wilson, Dover	Dover	June 21
Dist. of Col'bia	Geo. C. Ober, Washington	Washington	April 12
Florida*	J. D. Fernandez, Jacksonville	Jacksonville	April 4
Georgia	E. R. Anthony, Griffin	Atlanta	April —
Idaho*	W. F. Howard, Pocatello		April 5
Illinois	J. A. Egan, Springfield	Chicago	Jan. —
Indiana	W. T. Gott, Crawfordsville	Indianapolis	May 24
Iowa	Louis A. Thomas, Des Moines	Des Moines	
Kansas	F. P. Hatfield, Olathe	Topeka	Feb. 8
Kentucky	J. N. McCormack, Bowling Green	Louisville	
Louisiana	F. A. LaRue, 211 Camp Street, New Orleans	New Orleans	May 17
Maine	F. W. Searle, Portland	Portland	Mar. 8
Maryland	J. McP. Scott, Hagerstown	Baltimore	June 7
Massachusetts*	E. B. Harvey, State House, Boston	Boston	Mar. 8
Michigan	B. D. Harison, 205 Whitney Building, Detroit	Ann Arbor	June 14
Minnesota	W. S. Fullerton, St. Paul	St. Paul	May 10
Mississippi	S. H. McLean, Jackson	Jackson	May 10
Missouri	Frank B. Hiller, Jefferson City	Jefferson City	June 13
Montana*	Wm. C. Riddell, Helena	Helena	April 5
Nebraska	C. A. Carr, Lincoln	Lincoln	Feb. 2
Nevada	S. L. Lee, Carson City	Carson City	May 2
N. Hampshire	Henry C. Morrison, State Library, Concord	Concord	July 6
New Jersey	H. G. Norton, Trenton	Trenton	June 21
New Mexico	J. A. Massie, Santa Fe	Santa Fe	April 11
New York	C.F.Wheelock, Univ. of State of New York, Albany	New York, Albany, Syracuse, Buffalo	Feb. 1
N. Carolina	B. K. Hays, Oxford	Wrightsville	June 15
N. Dakota	H. M. Wheeler, Grand Forks	Grand Forks	April 5
Ohio	Geo. H. Matson, Columbus	Columbus	June 14
Oklahoma*	F. P. Davis, Enid	Guthrie	April 12
Oregon	B. E. Miller, Portland	Portland	July 5
Pennsylvania*	N. C. Schaeffer, Harrisburg	Philadelphia, Pittsburg	June —
Rhode Island*	G. T. Swarts, Providence	Providence	April 7
S. Carolina	H. H. Wyman, Aiken	Columbia	June —
S. Dakota	H. E. McNutt, Aberdeen	Watertown	July 13
Tennessee	C. A. Abernathy, Pulaski	Memphis, Nashville, Knoxville	May —
Texas	M E. Daniel, Honey Grove	Austin	June 28
Utah	R. W. Fisher, Salt Lake City	Salt Lake City	April 4
Vermont	W. Scott Nay, Underhill	Burlington	July 12
Virginia	R. S. Martin, Stuart	Richmond	June 22
Washington*	T. C. McFadden, Seattle	Spokane	July 5
W. Virginia	H. A. Barbee, Point Pleasant	Wheeling	April 12
Wisconsin	J. M. Beffel, Milwaukee	Madison	July 12
Wyoming	S. B. Miller, Laramie	Cheyenne	Feb. 16

*No reciprocity recognized by these States.

†Applicants should in every case write to the secretary for latest details regarding the examination in any particular State.

California.—In the future twelve questions are to be given on each paper, and the candidate is to select ten of these. Those who fail need not be reexamined in any subject in which they gained 80 per cent., provided they make up their deficiencies within a year.

Idaho.—At the recent examination there were 42 applicants, and of these 27 were successful.

Medical Items.

Contagious Diseases, Weekly Statement.—Report of cases and deaths from contagious diseases reported to the Sanitary Bureau, Health Department, New York City, for the week of January 8, 1910:

	Cases	Deaths
Tuberculosis Pulmonalis	503	177
Diphtheria	339	45
Measles	925	17
Scarlet Fever	525	36
Smallpox	—	—
Varicella	160	—
Typhoid Fever	57	13
Whooping Cough	34	5
Cerebrospinal Meningitis	5	4
Malarial Fever	—	—
Totals	2,548	297

Histological Modification by Tuberculous Poisons of the Medulla of the Bones.—Ernesto Patrone studied the action on the medulla of the bones of tuberculous poisons by injecting them subcutaneously in eight rabbits, which were killed some weeks later and the microscopical examination of the medulla of the bones made. The results showed that the tuberculous poisons in moderate doses cause an active hyperfunction of the medulla, independent of other factors. There was an increase of mononuclears and of myelocytes in the medulla.—*Annali dell' Instituto Maragliano.*

Health Reports.—The following cases of and deaths from smallpox, yellow fever, cholera, and plague have been reported to the Surgeon-General, Public Health and Marine-Hospital Service, during the week ended January 7, 1910:

			CASES.	DEATHS.

THE RECOGNITION AND TREATMENT OF ECTOPIC GESTATION.

BY CHANNING W. BARRETT, M.D.,

CHICAGO.

GYNECOLOGIST TO THE CHICAGO POLICLINIC SCHOOL AND HOSPITAL; ASSOCIATE PROFESSOR OF GYNECOLOGY, MEDICAL DEPARTMENT, UNIVERSITY OF ILLINOIS; GYNECOLOGIST TO HENROTIN MEMORIAL HOSPITAL; OBSTETRICIAN, COOK COUNTY HOSPITAL.

THE common saying that "A disease known is half cured," has no where greater significance than when applied to extrauterine pregnancy. The word picture of this pathological condition, that will lead to its clinical recognition, has not been painted. It is not that there is a lack of literature upon the subject, nor that valuable descriptions are wanting, but rather the difficulty of reproducing from didactic study a clinical picture which has such typical manifestations on the one hand and such wide and numerous variations on the other.

That the diagnosis is not made is shown by the fact that a large percentage of my cases have been previously treated as cases of abortion and further by Heineck in his study of cases at Cook County Hospital, in which hospital the cases if diagnosed go to the service of surgical obstetrics. He shows that in a series of thirty-two cases, twenty-five cases were operated in the general surgical service and seven cases in the service of surgical obstetrics.

It is with no thought of producing a more perfect picture, but rather to view the question from the angle of personal experience with a background of authenticity and, if possible, to stimulate the members of this society to a more ready recognition of the condition, that this paper is presented. That phase of the treatment which has been emphasized of late, namely, the nonoperative treatment when the patient is in collapse following rupture, also deserves careful analysis at the hands of this and every other body of medical men.

No exhaustive discussion of the etiology and pathology may be attempted at this time, and yet no study of the diagnosis and treatment is comprehensive that does not have a pathological foundation, and this again takes us back to pathological conditions existing before the pregnancy—the etiology. Tait and Schroeder and other early observers thought that extrauterine pregnancy had to be accounted for by some condition which allowed the spermatozoa to travel up the tube. They taught that the spermatozoa were carried to the uterine mouth of the tube by the upward wave of the cilia of the epithelium of the uterus, and that the ovum was brought to this point by the downward wave of the cilia of the epithelium of the tube. Hofmeier, Mandl, and others have shown that the current is downward from the outer end of the tube to the cervix and that the spermatozoa have to and do travel against this current from the cervix upward into the tube where pregnancy takes place. Our theories of etiology, then, do not have to account for the impregnation of the occasional ovum outside the uterus. Every pregnancy is to be looked upon as extrauterine in the beginning and we might justly question why so many ever reach the uterus. While the spermatozoa have motility and travel against the current created by the cilia, yet the current and tubal peristalsis are looked upon by most authors as having an important bearing in the migration of the ovum. The etiological factors, then, must be such conditions as will prevent or retard migration of the impregnated ovum, or such conditions as will furnish a more ready implantation of the ovum, or both.

We may have the migration of the ovum retarded or prevented by (1) absence or diminution of the cilial wave; (2) absence or diminution of peristalsis; (3) tortuosity; (4) constrictions, kinkings, and narrowing of the lumen; (5) blind pockets; (6) transmigration of the ovum; (7) tumors in the wall of the tube and polypi in the lumen of the tube.

Abel, Kreisch, Runge, von Franqué, and Garkish, and later Höhne, have laid stress upon congenital hypoplasia as an important factor in bringing about the above conditions. Dührssen attaches some importance to puerperal hyperinvolution as a factor in narrowing the tube and lessening peristalsis. Evidence is abundant, however, to show that infections of the tube and especially gonorrheal infections, with their resulting inflammatory reactions, are the frequent cause of the above conditions. Virchow, Schroeder, and Tait first pointed out the importance of this and their views were corroborated by a long list of able observers among whom may be mentioned Martin, Küstner, Olshausen, etc. Sixty-eight and seven-tenths per cent. of Dührssen's cases and sixty-six per cent. of Mandl and Schmidt's cases had had gonorrhea. Ott and Petersen's cases all gave history of inflammation. It is doubtful if the cilia are ever as agile in a tube once involved with gonorrheal infection, peristalsis is crippled, tortuosity is marked, constrictions, kinkings, narrowing of the lumen, and pathological pockets are marked features. There has been in my cases no etiological factor so prominent as previous pelvic disease and that previous pelvic disease in about seventy-five per cent. of cases was presumably gonorrhea. Mrs. H. developed an acute gonorrheal infection a few days after marriage. Severe tubal infection, with extensive reaction, more marked on left side. Two years later tubal pregnancy on right side with marked evidence of old inflammation. Large pus tube with outer end closed on left side. Mrs. S. prostitute—5½ month fetus, living. Extensive pelvic adhesions on both sides. Mrs. H. examined one year before extrauterine pregnancy occurred. Uterus retrodisplaced, tubes and ovaries

enlarged and matted together. Had had a previous operation. Feared extrauterine pregnancy and developed it one year later. Mrs. R. gave birth to a child seven months previous to development of extrauterine. Birth of child followed by acute pelvic inflammation on the right side, tubal pregnancy on same side. Mrs. F.'s first pregnancy was tubal on right side. At operation evidence of old adhesions was found on right and left side. Four years later operated for extrauterine on left side, etc., etc. Many women who have had gonorrhea are sterile because of closure of the tube or because the ovum fails to find lodgment, but of those cases in which the impregnated ovum finds attachment the percentage of extrauterine pregnancies far exceeds the percentage in women who have not had an infection.

It may be urged as a reason for extrauterine pregnancy in these cases that these tubes furnish a more ready lodgment than do normal tubes. But against this theory is the fact that a normal uterus furnishes a more ready lodgment for the ovum than the diseased uterus. It is not consistent to believe that the inflammatory process, which unfits the uterus for implantation of the ovum, will better prepare the tube to act the part of host. We are forced to the belief, then, that tubal inflammations play an important part in laying the foundation for a tubal pregnancy but that it does so by interfering with migration rather than furnishing a more ready field for implantation by reason of the inflammation.

Place of Implantation.—Tubal Implantation may occur at any point from the intrauterine portion of the tube to the extreme limits of the fimbria. It assumes a greater gravity as the attachment approaches the uterus. This led Dr. Joseph Price to give us the epigram. "Those implanted in the outer half of the tube belong to the surgeon, those in the inner half to the undertaker." It was once thought that all extrauterine pregnancies were primarily tubal but abundant evidence proves the contrary. Webster, who denied the possibility of an ovarian pregnancy, urged that implantation could only take place on Mullerian structures. Later, when convinced of the possibility of ovarian pregnancy, he explained it upon the grounds of inclusion of Mullerian structure in the ovary. A decidual reaction has been counted necessary for implantation by Webster and others, but upon this not all are agreed. That implantation does not take place more frequently in the tube, Webster explains upon the theory that the upper part of the Mullerian duct (the tube) as it has been differentiated into an egg transmitting portion, has lost its capacity for normal decidual reaction, and therefore its capacity for receiving the ovum, and that a decidual reaction in the tube is a result of reversion to an earlier type in which the whole Mullerian tract was used for the implantation of multiple ova. Sipple is of the opinion that a certain time is required for a decidual reaction to take place and that during this time the fertilized ovum has usually reached the uterus, but that in case of external migration the fertilized ovum may reach the tube when sufficient reaction has taken place as to allow of implantation. Again Hitschmann and Lindenthal are of the opinion that the ovum implants itself only at a certain stage of its development at which time it has usually reached the uterus but that an unusual delay finds it in the tube at the time ripe for implantation. The experimental work of Tainturier and others, upon rabbits, in which the tubes and horns of the uterus are tied indicates that in rabbits at least some other factor than mechanical obstruction is necessary for the development of the ovum in the Fallopian tube, and this they were inclined to ascribe to the lack of decidual reaction. These views are based upon the idea that decidual reaction is a preparation for, and necessary to implantation. This would imply that the maternal tissues are a willing host, anticipating the needs of its parasite, and this would imply a mutual benefit.

More recent investigations make possible the following statements: (1) Implantation of the ovum has taken place where Mullerian tissue does not normally exist. (2) Decidual reaction in the tubes, and to a less extent in the uterus, is a variable quantity—a well-developed decidual reaction having been observed in some cases and no decidual reaction having been discovered in other cases of extrauterine pregnancy. (3) Cells morphologically similar or identical to decidual cells have been observed in the uterus, in the tube, in the ovary, upon the peritonium at some distance from the tube, without pregnancy having existed. (4) The method of implantation of the ovum in the uterus and in the tube and the process of development indicate that the ovum is a parasite working at the expense and to the destruction of the maternal structures. (5) The decidual reaction is by many observers considered a connective tissue reaction of maternal structures not to receive the ovum but to withstand the destructive and corroding influence of the trophoblastic cells of the latter. (6) These observers consider that the greater damage done in the tube, over that done in the uterus, is due to its lack of ability to develop a protective tissue reaction.

Heinsius says that the decidua is a tissue consisting of a dense layer of enlarged connective tissue cells with large nuclei, a tissue the functions of which are to afford protection both to mother and ovum. Krömer has observed that the muscular fibers and the interstitial connective tissue cells swell in a decidual manner, and show large clear vesicular characters, when in contact with masses of syncytium. Langhans found a completely developed decidua only at the placental site. Williams coincides with Peters in the belief that the ovum penetrates the surface epithelium and burrows into the subjacent tissue. Heinsius again says that in what will be the placental site the muscle is destroyed and looks as if it had been eaten out. Füth remarks that the ovum undoubtedly enters the tissues by its own activity. Vassmer and Raschkes are authority for the statement that the fetal cells destroy or cause atrophy of the muscle—the presence of muscle in the capsule showing the deep implantation in the tube wall. Andrews says "all observers except Veit, Krömer, and Fellner are agreed that the maternal tissues are destroyed by the trophoblast. As proof of this destructive action in the case reported, the trophoblast had grown through the capsularis and attacked the tube wall on the other side of the lumen." Again he remarks, "The bulk of evidence is in favor of the view that the fetal cells act in a malignant or pseudomalignant manner toward the maternal tissues. Hitschmann has observed the trophoblast actively invading the blood-vessel walls. Veit refuses to admit this and thinks these findings only in veins and due to deportation, but Andrews quotes numerous authors who are of the opinion that the deportation is secondary to destruction of the vessel walls by the trophoblast. Williams, after quoting numerous observers, says, "It is apparent that while a decidual reaction may occur in the tubes, in tubal pregnancy it is not universal and never

develops to the same extent as in the uterus. This fact is of interest not only from a scientific point of view, but also has a distinctly practical bearing, as it would seem to offer a satisfactory explanation for the invasion and destruction of the tube wall by the fetal elements. In uterine pregnancy such an invasion is noted only in the rare instances in which there is imperfect development of the decidua, and it would therefore appear that one of the main purposes of the latter is to protect the underlying maternal tissues against the invading and corrosive action of the fetal elements." Werth, as long ago as 1887, looked upon extrauterine pregnancy as a malignant growth but says that the ovum in "making its bed digs its own grave." Haultain says, "A tubal pregnancy must be considered in the light of a malignant growth and a continued menace to life as long as it is present." Were it necessary quotations could be multiplied in support of the view that the ovum is a parasite in the tube doing harm not alone by the failure of the tubes to keep pace with its growth, but by the destruction of maternal tissues as well. Almost every observer must have noted cases in which the perforation has a distinct punched-out appearance as though the ovum has literally eaten its way through the tube walls.

Tubal Pathology.—Beginning with such pathology as exists at the time of fertilization such as changes in the epithelium, thickening of the tube wall, partial closure of its mouth, tumors in its wall or projecting into its lumen, congenital or acquired narrowing, tortuosity, blind pockets, kinkings, etc., or almost no pathology at all, we have a series of characteristic changes due to the ovum imbedding itself at the expense of the maternal tissues and then corroding its way out of this bed at the further expense of its surrounding sac, many times opening up such blood vessels that hemorrhage results in the death of the host.

Werth and others are of the opinion that the ovum may become implanted upon a fold of the tube or between two folds, and designates the implantation columnar or intercolumnar accordingly. In either case the ovum penetrates the lining of the tube and burrows beneath the mucous membrane as is shown by the experimental work of Graf Spee upon implantation in the guinea pig, and the observations of Peters in an early pregnancy. A well-marked pseudoreflexa has been observed separating the tubal pregnancy from the lumen of the tube. The trophoblastic cells invade the surrounding maternal tissues, according to Williams, and many others. In the uterus this invasion is met by a well-marked decidual reaction and hypertrophy and hyperplasia of muscle cells, but the tubal tissues having little capacity for such reaction are overcome and suffer degenerative changes.

Peters, von Franqué and Garkisch, Heinsius, Hitschmann, Andrews, Williams, and many others believe in this destructive action of trophoblastic cells of the ovum and the inability of the tube to withstand it. Williams writes, "The trophoblastic cells not only possess markedly invasive properties in virtue of their rapid proliferation, but also exert an erosive action upon the surrounding maternal tissue. As a consequence, many of the muscle cells are destroyed and undergo fibrinous degeneration, while the blood-vessels in the vicinity are opened up to the invading trophoblast and by the escape of their contents give rise to a large number of spaces of varying size, filled with blood, which lie entirely within the trophoblast or between it and the surrounding maternal tissue." The action of the trophoblast may invade the maternal blood-vessels to such an extent that the resulting hemorrhage may partially or entirely separate the ovum from its attachment, resulting in death of the ovum even at an early date. Numerous cases are observed in which section of the tubal contents shows the mass to be made up of concentric rings of partially organized blood clot with possibly the dead and compressed ovum in the center—a tubal mole. In the progress of a living ovum, or the enlargement of the tubal mole by repeated hemorrhage, the tubal wall becomes thinned, degenerated, and eroded, when it gives way and the ovum is carried outside the tube, or from its sac into the tube lumen. The hemorrhage into the sac, thereby increasing the pressure, as well as the above-described degeneration of the sac, is considered to have an important bearing upon final rupture. An ovum implanted near the adominal end of the tube is much more likely to rupture through the pseudoreflexa into the tube lumen where it may continue for awhile, when it may be aborted into the abdominal cavity. The tube wall may give way upon its peritoneal surface or at its broad ligament site. With the onset of pregnancy the entire blood supply of the pelvic organs is increased. In tubal pregnancy the vascularity of the tissues is marked so that erosion and rupture result in extensive and oftentimes dangerous hemorrhage, depending upon the degree of vascularity, the coagulability of the blood, and the surrounding adhesions. It frequently happens that an inflammatory reaction has preceded the rupture so that a wall of adhesions confines the blood and limits the amount of hemorrhage. Occasionally, the tube has shown such capacity for hyperplasia and hypertrophy of its musculature and connective tissues that it has continued unruptured to full-term pregnancy, but this is the rare and unexpected exception. The future of the tube has been of much interest. Added to the previous pathology of the tube, we have the more or less ragged cul-de-sac or perforation, oftentimes hypertrophy and hyperplasia, some degeneration, edema, and inflammatory thickening, adhesions at times and the remains of portions of the ovum, to make a future pathological tube. Occasionally, however, repair takes place to the extent that a fairly healthy tube is left.

The Fate of the Ovum.—It is not unlikely as indicated by the experimental work of Schmidt, Tainturier, and Mandl upon rabbits that many fertilized ova failing to find their way into the uterus, also fail to become imbedded and die. In a few cases the ovum becomes implanted but its destructive action causes hemorrhage which detaches it, and it remains in the tube for a time, causing only a moderate disturbance, and finally becomes absorbed. A large number die sooner or later from hemorrhage around them, but rupture through their capsule into the lumen of the tube or through the wall of the tube into the broad ligament or into the peritoneal cavity. The live ovum or the tubal mole, if situated near the abdominal end of the tube, may be aborted from the end of the tube with the primary rupture or later after finding temporary lodgment in the tube lumen. If the pregnancy is situated in the uterine end of the tube, abortion of the dead or live ovum may occur into the uterine cavity. The live ovum may retain enough of its original attachments to continue circulation and new attachments may be formed in the uterus, or failing in its attachments, the ovum will die. A live ovum rupturing into the broad ligament,

or into the peritoneal cavity, or one aborting into the peritoneal cavity may at once die from lack of circulation or may continue to live until a subsequent rupture or series of ruptures severs it from its blood supply sufficiently to cause death. In a few cases the ovum continues to term after rupture, and cases have been known to continue to term without rupture. The products of an early pregnancy may, if the patient lives, become absorbed or encysted or suppuration may take place. Later the death of the ovum may be followed by suppuration, mummification, or calcification, or be transformed into a fatty degenerated mass. The remains of full-term retained fetus has been removed in many instances recorded by Leinzell, Keozer, Albers, Kuchenmeister, Fales, and others. It has proven the source of dystocia in a future pregnancy, leading to cesarean section, induction of premature labor, or craniotomy in the hands of Hugenberger, Schauta, Sänger, Hennigsen, Debot, Stein, and others. A retained fetus may find its way into the bladder, bowel, rectum, vagina, or through the abdominal wall months or years after death of the fetus. In a considerable number of cases the living fetus has been removed by surgical measures.

Williams has shown in a series of thirty-five collected cases of what he terms, positive, highly probable, or probable ovarian pregnancies, eleven cases went to full term. As pointed out by this author, this would indicate a greater degree of tolerance on the part of the ovary than is shown in the tube. However, in ovarian pregnancy rupture must be the expected outcome as shown by the same series of cases. The ovum is subject to the same diseases that are found in uterine pregnancy, hydatiform mole, (Recklinghausen, Otto) Hydramnios (Teuffel, Webster) and deciduoma malignum (Ahlfeld, Marchand). The patient, too, has been known to suffer from the toxemia of pregnancy resulting in eclampsia. The prognosis of the fetus is so unfavorable that taken with the extreme risk to the mother, our treatment should not brook delay in the interest of a nonviable child. The probable fate of the mother could well be discussed but this is so influenced by treatment at the present time that it will be discussed under that subhead.

The Recognition. The diagnosis of extrauterine pregnancy is made most readily by having in mind a typical picture with exceptions and a clear-cut clinical picture of those things which simulate it. A wide clinical experience in this and diseases simulating it is the best possible preparation, but it is not for this person we are writing upon the subject. I would lay great stress upon a carefully taken history. A history taken by a careful observer, an observer alive to the possibilities of extrauterine pregnancy and conditions which simulate it. A carelessly taken history by one not having the possibilities in mind, may not give even a suggestion of the trouble to the careful reader of the history. Many patients have to be questioned closely and cross questioned in order that truth be revealed. One magnifies and another minimizes the pain.

Usually the presence of pregnancy is suspected, the clinical course of which is modified by the pathology which develops by reason of the implantation taking place in the tube, the resulting rupture furnishing a strong diagnostic feature as well as introducing a great element of danger. The typical picture is presented by (1) a woman of childbearing age, the age of greatest frequency corresponding to the age of greatest frequency of pregnancy; (2) marital relations—this history is sometimes withheld; (3) a history of previous sterility—many exceptions; (4) a history of previous pelvic disease—few exceptions; (5) a history of probable pregnancy —some exceptions; (6) the course of the pregnancy modified or apparently interrupted; frequently more pain, pelvic distress, nausea, etc., before rupture takes place; (7) sudden outset of severe pain with hemorrhage and collapse, variable in degree; (8) the above frequently a mistaken history of abortion —a large number of my cases had been previously curetted; (9) symptoms keeping up or returning after a supposed abortion or curettage; (10) a boggy pelvic mass—occasional exceptions; (11) a distinct tubal enlargement without a surrounding boggy mass, if seen before rupture, in a few cases when seen after a history of rupture; and (12) a normal, subnormal, or only slightly elevated temperature. With this history, an extrauterine pregnancy is to be taken into consideration. The patient is now closely questioned as to the last regular flow and the fact of regularity or irregularity for several months back established and any abnormalities carefully noted. The date of onset of pain and hemorrhage also noted. A flow followed by pain is not typical. A sudden severe pain, followed by moderate external hemorrhage, is typical, but may be met in abortion or pelvic inflammation. The patient frequently evidences greater shock and anemia than is suggested by the external hemorrhage. A sudden onset of pain not followed by hemorrhage to a slight or moderate extent is not indicative of extrauterine pregnancy. With a history of recent pelvic pain simulating that accompanying rupture of extrauterine pregnancy, and with a mass found in the pelvis, but in which no red blood or prune juice or tarry discharge had been discovered, I would make a probable diagnosis of some other condition than tubal pregnancy; but this might, if the evidence of extrauterine pregnancy was strong, be ovarian pregnancy in which the hemorrhage is not so marked. Patients' interpretation and memory of pain is so variable that it is well worth while asking (1) "What were you doing when you noticed the first pain?" and then, in order to reveal the severity and length of the pain, (2) "What did you do after you noticed the pain—did you continue with your work—did you keep about or did you have to go to bed, and did you send for a doctor, etc.?" The patient is then carefully accompanied over the whole course of her trouble, day by day, and every occurrence noted. We have found in the study of the pathology that the destructive action of the trophoblast upon the tubal wall and upon the blood vessels, the resulting hemorrhage causing increased pressure, and distension of the tube from growth of the ovum, all played a part in the rupture. The answers I have received to question one indicate that efforts on the part of the patient play no small part in the final rupture. One patient was straining at stool, two were hanging up clothes, one was reaching up from a step-ladder, one was sweeping, and one stooped to go under a barbed-wire fence, fell, overcome with pain, and had to be carried to the house (Dr. Peterson's case). On the other hand, some were lying quietly in bed or sitting without exertion. In most cases the onset of pain was so marked as to cause the patient to leave her work but to this there was exceptions. One continued hanging up clothes until through, one lay down for a few minutes and then resumed work about the house for the day. Many writers have tried to lay stress upon some one thing that would

clinch the diagnosis of extrauterine pregnancy and to this end have laid much stress upon the finding of decidua. Rossi Doria, Schmauch, Hitschmann, and Adler, and others point out that there is no distinctive decidual cell. A decidual reaction is found in the uterus in uterine pregnancy, may be slight or marked in extrauterine pregnancy and has been described by Griffiths and Dakin and others with no pregnancy, so that the findings of a decidual tissue is little more than suggestive and the absence of decidual findings of very little negative importance. In case of a probable pregnancy, with uterine hemorrhage, pelvic pain, and a pelvic mass, in which the question lies between abortion and extrauterine pregnancy, a decidua with chorionic villi would indicate a uterine pregnancy while a decidua without chorionic villi would suggest an extrauterine, although the first might be due to a tubal abortion into the uterus. In undertaking to differentiate between abortion and extrauterine pregnancy, the sudden, severe, lancinating, or tearing pain accompanied by collapse and hemorrhage or followed by hemorrhage with an anemia in excess of external flow, the pain not being of a spasmodic nature, speaks for extrauterine, especially with uterine shreds with no evidence of an ovum. Here one should bear in mind, too, the possibility of a combined intra- and extrauterine pregnancy. Practically every case of supposed abortion should have a careful pelvic examination to discover the presence or absence of complicating conditions. The observer should not be thrown off his guard in cases giving a history of attempted abortion. The coroner's records instance a case in which an abortion was attempted, which resulted in infection from which the patient died. The coroner's physician found an extrauterine, but no intrauterine pregnancy. The operator is now serving a term in prison. A woman entering my service at Cook County Hosiptal, who died shortly after her arrival, gave the history of pregnancy and attempted abortion with emmenagogues and supposed that she was aborting. The interne found her in severe collapse with anemia out of proportion to evidences or history of external bleeding and diagnosed extrauterine pregnancy but too late for operation. The coroner's physician found rupture of the right tube with the abdomen full of free blood. An interesting medicolegal case is recorded in which a pregnant woman on a journey to a remote part of the country was injured by a railroad accident while yet in civilization. Her injury resulted in supposed abortion, but complication led to the necessity of a colotomy, at which time an extrauterine pregnancy was discovered. The interested parties sought to recover damages from the railroad, but the jury rendered a verdict for the defendant on the ground that had the woman gone to an isolated territory, where only unskilled aid was at hand, the extrauterine pregnancy would no doubt have resulted in her death.

The most severe cases in which the physician is called during the attack are frequently not difficult to diagnose. A woman of childbearing age, with or without history of sterility, with or without a history of previous pelvic disease, with or without a history of presumable pregnancy, who is taken with sudden severe pain and collapse with evidences of intraabdominal hemorrhage, has in all probability an extrauterine pregnancy with complete or partial rupture, or tubal abortion, and in a large proportion of these severe cases will lose her life unless prompt operative treatment is instituted. A number of these cases will be met in which no pelvic mass is discoverable to verify the diagnosis. A condition which very closely simulates the feel of a ruptured extrauterine mass is a retrodisplaced pregnant uterus, but the mass is more distinctly continuous with the cervix, more central and symmetrical, is not accompanied with uterine hemorrhage unless abortion is threatening, gives a history of gradually developing pelvic distress, more and more difficulty in obtaining bowel movements, and gives, usually, if seen when incarceration is beginning, or continuing, a very definite history of bladder symptoms. There is usually absence of history of sudden severe pain and collapse. In extrauterine pregnancy we seldom get marked bladder symptoms or retention of urine as in incarceration. The two pictures are sufficiently unlike to be readily distinguished by the initiated.

Torsion of the pedicle of an ovarian cyst or a fibroid or the omentum may stimulate extrauterine pregnancy, but these would usually lack the sudden collapse and evidences of loss of blood characteristic of extrauterine pregnancy, and the hemorrhage from the uterus would be wanting in most cases.

Appendicitis and extrauterine pregnancy are not infrequently confused. In the latter the greatest tenderness is elicited usually by bimanual examination, while pressure over McBurney's point reveals the tenderness in appendicitis. In appendicitis, too, we lack the collapse which goes with an equally severe attack of extrauterine pregnancy; anemia is not so marked; a rise of temperature is a marked feature; a more marked leucocytosis is soon found in appendicitis, and there is absence of hemorrhage from the uterus, unless a mere coincidence when the onset of the pain usually bears no definite relation to the onset of the hemorrhage. Early uterine pregnancy, accompanied with ovarian growth, or tubal enlargements, should be kept in mind. In advanced cases we should remember the possibility of an abdominal pregnancy and intrauterine pregnancy, or large ovarian growth, a fibroid tumor or ascitis, etc. A number of cases are recorded of combined intra- and extrauterine pregnancy both going to term.

Many times, after taking all diagnostic points into consideration, the observer is still in doubt as to the presence or absence of extrauterine pregnancy. In order to determine whether a given pelvic mass is a pregnancy or otherwise, a vaginal puncture or aspiration is sometimes carried out. This is to be condemned in the face of evidence that it has resulted in death in a number of cases, and is permissible, if at all, only when the operator is prepared for an immediate laparotomy, and even then an abdominal incision discovers more and offers greater opportunity for checking any severe hemorrhage which may follow interference with the sac. The use of the *x*-ray may be useful to discover the fetal skeleton in some doubtful cases.

Early observers consider pelvic hematocele unrelated to extrauterine pregnancy of frequent occurrence, but the work of Veit, Tait, and others demonstrated that it usually had its beginning in the form of pregnancy. Bovée and others now point out that the pendulum has swung too far in considering all pelvic blood collections a result of extrauterine pregnancy, whether in the tube, ovary, broad ligament, or lower peritoneal cavity. The question arises as to what establishes the fact of

extrauterine pregnancy when the abdomen is opened or in examination of specimens removed; certainly not the presence of blood, whether circumscribed or free, nor the presence of decidua, but rather the finding of undoubted macroscopical evidences of the ovum or the microscopical finding of chorionic villi or some other portion of the ovum. The presence of free or circumscribed blood with a rupture of the tube or ovary is strong presumptive evidence, without the ovum being discovered, but the prsence of chorionic villi, observed microscopically, establishes the diagnosis.

Treatment.—In many of the abnormalities of pregnancy the life of the fetus as well as that of the mother has to be considered. So nearly certain is the ovum to commit suicide in extrauterine pregnancy, however, that only the mother's health and safety have to be considered in any but the exceptional case. As one of the reasons for inducing abortion, an aspirant for one of our large hospital services gave in competitive examination this answer: "In cases of maternal syphilis, abortion should be induced in the interest of the child." The prognosis is so bad for the ovum in extrauterine pregnancy that we could almost apply a similar form of treatment in the interest of the fetus. The mortality of the fetus is 100 per cent. without operative measures, most cases resulting in death of the fetus in the early months. In those few cases in which the ovum continues to term, the interest of the child and mother are one, that is separation. We have abundance of pathological and clinical evidence to show that, with the imbedding process of an extrauterine pregnancy, begins the work of a parasitic growth likened to a malignant growth, destructive to the maternal tissues, and at all times unfriendly to its host until it is not only dead, but removed. The tendency of the growth is suicidal, but in accomplishing its self destructive work it is matricidal in its tendency.

We have then but to consider the best interest of the mother, and to decide what may be expected if the condition is left to its own undoing; what may be expected of the measures which undertake to kill the ovum; what may be expected of surgical measures, and when may surgical measures be expected to accomplish most.

Extrauterine pregnancy is not in any sense a medical disease. No drug treatment or rest or manipulation or Christian science may be expected to postpone indefinitely the almost inevitable rupture, or prepare the patient so as to make the rupture safe. Not all cases will die from rupture, but we have few or no facilities for determining which ones will prove fatal. If the hemorrhage following rupture takes place in the broad ligament or is circumscribed by adhesions, the danger is lessened, but that cannot be prophesied before rupture, and very frequently cannot be discovered afterward without operation, and even if properly diagnosed a secondary rupture may take place later. An ice bag or "absent treatment" is a very poor substitute for a ligature in intraabdominal hemorrhage. Any delay after a diagnosis of extrauterine pregnancy is made makes possible further rupture, greater hemorrhage, the introduction of bacteria, and the formation of attachments which may prevent immediate hemorrhage, but lead to a more complicated operation later. Extrauterine pregnancy is distinctly a surgical condition. Efforts have been made to destroy the life of the ovum by puncture, removal of amniotic fluid, injection of irritants or poisons, the use of electricity, and later the *x*-ray. These are uncertain as to causing death of the ovum and unreliable as to harm which they may do. Then, too, we have an abundance of evidence that the dead ovum is only slightly less harmful, if at all, than the living. The enlargement of the ovum from actual growth is only one of the causes of rupture. Degeneration of the sac and hemorrhage within the sac are quite as important factors to be considered. These uncertain forms of treatment cannot in any sense displace surgery, and the results to be attained preliminary to an operation do not compensate for the risk assumed in the delay of operative work. We have before rupture an active destructive growth which should be removed; we have after rupture hemorrhage, with blood vessels to be tied; we have material foreign to the peritoneal cavity to be removed; we have in some cases sepsis, for which should be furnished an exit. This is but following the most simple and yet the most important principles of surgery. Most fatal cases die from hemorrhage. The patient is sometimes seen in collapse, but this is due to hemorrhage and not the shock of trauma. In crushing injuries amputation after reaction from shock is thought best, but this delay is advised when hemorrhage is controlled. In intraabdominal bleeding the shock is due to blood loss, and we have no certainty that it is checked. Schauta collected 123 cases operated upon with a mortality of 5.7 per cent., and 121 cases treated palliatively with a mortality of 86.89 per cent. The statistics of A. Martin show a mortality of 63.1 per cent. out of 265 cases treated palliatively, and a mortality of only 23.7 per cent. of 515 cases treated operatively. The same author claims a mortality of 83.1 per cent. for patients with internal hemorrhage. Costun reports a maternal mortality of 85.5 per cent. Parry reports 174 cases of rupture in which none recovered. Chogan reports 84.4 per cent. recovered in cases operated upon, and Newell, 81.4 per cent. in 69 cases. Tinsteur's statistics treat of 133 cases as follows: 107 cases treated by laparotomy with 2 deaths; 22 cases treated vaginally with 3 deaths; 4 cases treated by the combined methods. Fifty of these cases were tubal abortions with 1 death and 23 ruptures with only 2 deaths, notwithstanding the fact that 5 of the cases of rupture were operated upon in collapse without anesthesia. Gobiet reports 18 cases of extra- and intrauterine pregnancy combined, of which 8 mothers recovered and 10 died; of the 10 which died only 2 were operated upon. Jacobs reports a series of 802 cases with intraperitoneal hemorrhage, 615 of which were operated upon during the first hours of accident with the result of 580 recoveries and 27 deaths; 142 cases were operated upon from several hours to one or two days after rupture, with 130 recoveries and 12 deaths; 45 cases were not operated upon, of which 20 lived and 25 died. My clinical experience is in accord with these figures and entirely in favor of early operative procedure. Out of a limited experience of 12 cases, 11 cases operated upon recovered, 1 case died after entering the hospital before operation could be performed; an early diagnosis and prompt treatment would undoubtedly have saved this one. I have quoted authors at some length because recently there was spread through the literature views, based upon animal experiments, at variance with clinical evidences, which clinical evidences are entirely in accord with the pathology

of the morbid process. The evidence is strongly in favor of not only operation but early operation as well. Robb discredits the clinical evidence, ignores the pathology, overrules the sound surgical law that bleeding vessels should be tied, because a series of dogs lived in spite of severed vessels. It is not my wish to minimize the value of animal experimentation or discredit the observer in this line, but conclusions must not be too readily drawn, and when the experience of the world for generations is that women do die from hemorrhage following the rupture of an extrauterine pregnancy, one must not be too hasty in abandoning immediate operation upon the grounds that hemorrhage will cease before sufficient amount of blood is lost to cause death. To quote Robb, "In none of these cases did the dog succumb to the hemorrhage, although we probably subjected our animals to as great a risk of bleeding to death as is incurred from a ruptured tubal pregnancy." The fact that a postmortem reveals a smaller percentage of blood per body weight than an animal is capable of losing and therefore less than is sufficient to cause the death of the woman has little weight against the fact that she is dead, and the further fact that great numbers die. The very fact that all of the dogs lived disproves the statement that they were subjected to as great risk of death from hemorrhage as is incurred by the average woman with ruptured extrauterine pregnancy. It is admitted that dogs can lose a greater percentage of blood. The great number of deaths following the slipping of a ligature in early work upon the pelvic organs proves, when compared with these experiments, the greater tendency of the ovarian and uterine arteries to bleed in women. The vascularity of the tissues and the size of the blood vessels are markedly increased during pregnancy, and these experiments were nearly all on nonpregnant dogs. But had greater pains been taken to have similar conditions obtain; and had pregnant dogs all stood the test, we would still have the undisputable fact to face that patients do die and are dying from ruptured extrauterine pregnancy and the way to save them is by early recognition and the application of a ligature. Robb's experiments led him to lay great stress upon the hemoglobin reading as a means of determining the time of formation of clot with the cessation of hemorrhage, and concludes as follows: "I believe that the hemoglobin readings will be found very useful in cases of intraabdominal hemorrhage from a ruptured ectopic pregnancy, and that when we see that the hemoglobin remains stationary, we can feel confident that we are doing the best for the patient in not operating at once." Crile's animal experiments showed a lack of such uniform results as could be turned to a practical purpose by estimating the amount of blood that could be lost. The mortality of extrauterine pregnancy is furnished largely by hemorrhage, and that percentage is large. Every fatal case passes through the condition in which Robb and others recommend nonoperative treatment on the grounds that hemorrhage will cease before death occurs. These authors look forward to an operation, but in just those cases in which a ligature is most needed operation is postponed because the patient is not strong enough to stand an operation. The patient is in shock because of loss of blood, and the essentially important step is to check the flow of blood before the fatal amount is lost. Practically every fatal case of extrauterine pregnancy has a period between rupture or partial rupture and death in which a life-saving operation can be performed. Every case faces the chances of a fatal hemorrhage. The pathology is such that no case with extrauterine pregnancy can be said to be safe. Some conditions are less dangerous than others, but it baffles diagnostic skill to say which ones are to be the fatal ones. No one can say when an unruptured case is going to rupture, or where it will rupture, or how fatal that rupture will be. No one can say in all cases, after rupture, whether that rupture is partial or complete, where the rupture has taken place, how liable it is to prove fatal, or when another rupture will follow, resulting in a further loss of blood, although the primary hemorrhage has been checked. Whether or not the primary hemorrhage has been checked is difficult to say. Rupture into the broad ligament is considered less dangerous because circumscribed, but the wall may at any time give way. This limiting wall and contained clot may be all that is preventing a fatal hemorrhage. Only in old cases and resulting pelvic abscesses should such a condition be attacked through the vagina, where we are practically helpless in the presence of hemorrhage.

The treatment of extrauterine pregnancy does not have to consider the ovum in the least until advanced pregnancy, and then the interest of the mother is the interest of the child. The fate of the mother is so precarious from the time of implantation of the ovum until its removal that immediate or early removal is the only rational treatment for extrauterine pregnancy, when a probable diagnosis has been made. The more marked the collapse the more urgent is immediate operation. Some will say this encourages emergency operating by unskilled operators, with improper surroundings, to which I would answer that this not a paper upon what to do with unskilled operators. Incidentally, we fear that were Oliver Wendell Holmes alive at the present time he would revise his statement to include these operators, "that if all drugs—with a few exceptions—were cast into the sea it would be better for man but worse for the fishes." We sometimes find it difficult enough to decide what to do when we have an operator and proper surroundings, and it is the business of all to make skill and surroundings fit the needs of patients as nearly as possible.

In combined intra- and extrauterine pregnancy the extrauterine ovum should be removed in the interest of the mother and the intrauterine embryo. Cases have been observed in which both came to term and were delivered alive, but the fetal and maternal mortality is necessarily high. Hanna Christer Nilsson, after a study of 68 cases of combined pregnancy, observes that interruption of the intrauterine pregnancy has little effect upon the extrauterine ovum, but that early removal of the extrauterine favorably influences the possibility of the uterine ovum going to term. Gobiet recommends that in case each has gone to term laparotomy should be performed after the delivery of the intrauterine child.

Martin, Dührssen, and others have recommended attacking the ruptured or unruptured extrauterine pregnancy through the vagina, but when we consider that the danger of lighting up new hemorrhage during an operation is great, with which we are unable to cope through the vaginal route, we find that anatomy, pathology, clinical evidence, and the surgical preference of a large number of men are

against this method of attack. My experience with the vaginal route has been slight, but had I early known, as I do now, how utterly helpless we were in the face of hemorrhage, my experience with the vaginal route would be less. It is highly undesirable in the newly ruptured cases, and in old cases the toilet of the pelvis can be made more perfect by the abdominal route except in the cases of sepsis or accumulated pus.

A. Martin, Prochownik, Ries, and others have advocated saving the affected tube, but this seems of doubtful utility. An occasional extrauterine pregnancy recurs on the opposite side, but not with sufficient frequency to warrant removal of an apparently healthy tube. Frequently a hydrosalpinx or a pus tube is found and should usually be removed. In two of my cases retrodisplacements were corrected at the time.

In conclusion, I would say: 1. In a study of implantation and the growth of the ovum there are grounds for the conception that the ovum is a parasite living at the expense of its host.

2. Previous pelvic disease, frequently of gonorrheal origin, seems to play an important part as an etiological factor.

3. A study of the pathology indicates that in the case of extrauterine pregnancy the parasitic growth develops malignant tendencies due to the incapacity of the maternal tissues to cope with it.

4. The extrauterine ovum is suicidal and matricidal in its tendencies.

5. The risk to the mother is largely though not entirely that of hemorrhage.

6. Less frequent causes of death or morbidity are, sepsis, obstruction of bowels, embolism, fistulæ, etc.

7. The prognosis for the ovum is so uniformly bad that it should receive no consideration except in cases of a viable embryo, when early removal should be urged in the interests of both mother and child.

8. The menace of extrauterine pregnancy to the life and health of the host is so great that an early diagnosis and prompt removal of the ovum is of prime importance.

9. An extrauterine pregnancy should be thought of when a woman of childbearing age gives the history of sudden, severe pain in the region of the ovary with a "show" or hemorrhage from the uterus, accompanied by collapse, and evidences of concealed hemorrhage, a pelvic mass helps to confirm the diagnosis.

10. The more urgent the sumptoms, the greater the need of operation as the collapse is due to hemorrhage and vessels may still be bleeding or hemorrhage may be resumed.

11. The clinical evidence is that patients do die of hemorrhage, experiments upon dogs to the contrary notwithstanding.

12. Pathology indicates, and clinical evidence teaches, that prompt surgical measures will decidedly lower the mortality.

13. Suprapubic instead of vaginal incision should be chosen in all unruptured cases, and in most old cases unless contraindicated by sepsis or pus accumulation.

14. No vaginal puncture or exploration should be undertaken for diagnostic or therapeutic purposes unless preparations have been made for immediate laparotomy.

A SIMPLE AND INEXPENSIVE PORTABLE POLYGRAPH.*

By WILLIAM N. BERKELEY, M.D.,

NEW YORK.

ATTENDING PHYSICIAN AT THE GOOD SAMARITAN DISPENSARY.

James Mackenzie's now classical studies of the venous pulse have thrown so much new light upon the theory of cardiac irregularities that no serious student of the subject nowadays can afford to be without a polygraphic apparatus of some kind. I have no words of aught but admiration and praise for the mechanical ingenuity and accuracy of the instruments now in use—such as Jaquet's, Uskoff's, Mackenzie's, and Gibson's. They are, however, of complicated construction, and when the import duty is paid the prices in this country run from $70 to $250.

I have therefore tried to devise something more simple and less expensive, and the machine shown to-night meets, I believe, both these requirements. While not adapted to exact laboratory researches, it seems to supply almost all clinical needs, is readily repaired, and costs at the outset only a tithe of the

Fig. 1.—Berkeley's Multiple Pulse Recorder, with parts assembled.

cheapest portable polygraph now in use that I know of.†

My machine will write the apex-beat or the carotid pulse or the jugular pulse or the respiratory curve, separately, or any two of these simultaneously. With a funnel of suitable shape it will also write hepatic pulses when these are present. Such a funnel adds much to the bulk of the apparatus, however, and inasmuch as there is no practical clinical question touching the hepatic pulse that cannot be answered by a jugular sphygmogram, a liver-funnel is not furnished except on special order. With large, flat wrists the radial pulses are also written with considerable clearness, but ordinarily the carotid and jugular pulses are the essential ones to be known, and it is these which my instrument is specially meant for.

The photograph explains most of the details. It shows the instrument with parts assembled. In the center in front are the two receiving funnels. They are covered with air-tight diaphragms of thin rubber dam. Across the center of one diaphragm is cemented a small half-cylinder of wood. This is laid lengthwise along the left carotid in the upper part

*Shown at the meeting of the Medical Section, New York Academy of Medicine, November 16, 1909.

†For sale by James T. Dougherty, 409 West Fifty-ninth street, New York.

of the neck, while the funnel is held steady by buckling the button-holed strap around the neck over the thyroid cartilages. The adjustment should

Fig. 2.—Healthy adult; carotid above, respiratory curve below.

be firm, but not tight enough to give the patient a sense of strangulation. If the apex is to be written, the same funnel is held with the fingers so as to

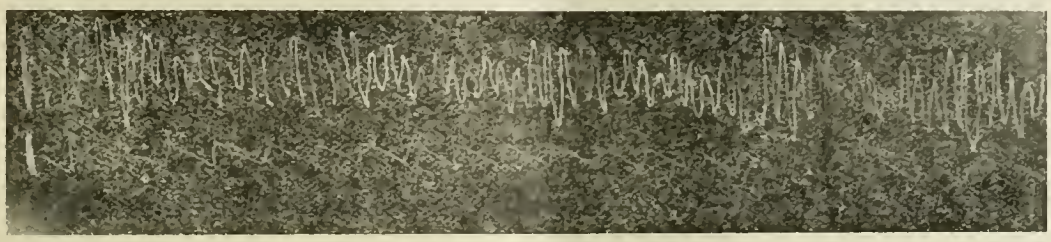

Fig. 3.—Anemic young man; carotid below, jugular above; jugular waves very large, and varying with respiratory movements.

bring the pad just over the pulsating apex of the left ventricle, the long axis of the pad lying in the proper costal interspace, parallel with the adjacent ribs.

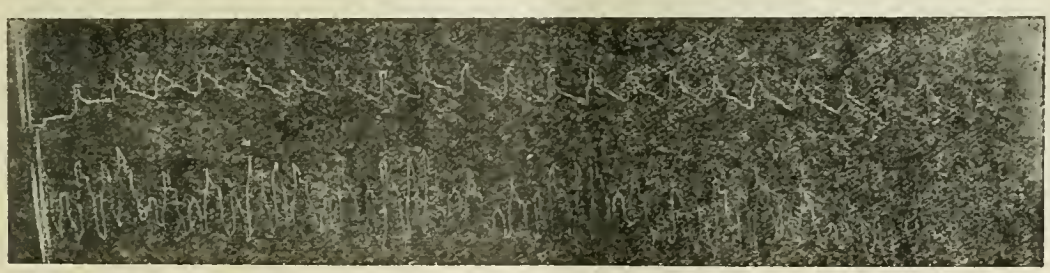

Fig. 4.—Anemic boy of 19 years; recently operated on for piles; carotid above, jugular below.

The other receiving funnel is designed for the jugular vein, or for respiratory curves. It has no pad. For the jugular pulse it is held with the fingers, just

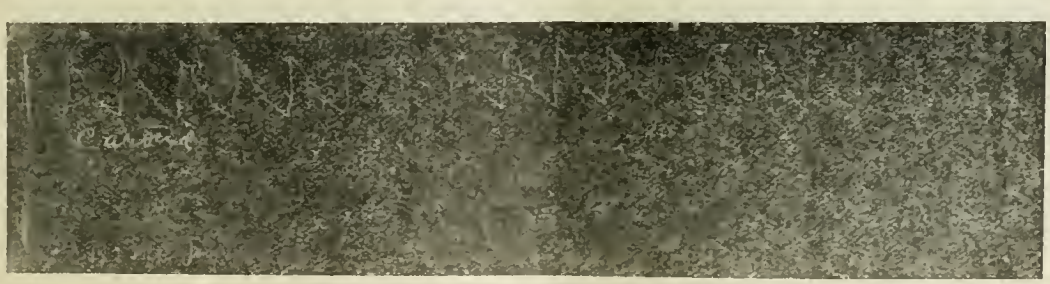

Fig. 5.—Youth of 22 years, healthy; jugular shows very large carotid wave and marked respiratory curve.

above the inner end of the right clavicle, and external to the sternal insertion of the sternomastoid muscle. As a usual thing the patient reclines upon a soft support, and he should relax his cervical muscles as much as possible, and breathe very lightly. For the respiratory movements the same funnel is to be held over the pit of the stomach. An assistant is helpful, but I have found that the patient himself makes a very good assistant, if he is intelligent and is interested in the success of the procedure.

From six months' experience with my instrument, I should say that about 75 per cent. of all patients examined give a good jugular tracing with this funnel, and this percentage compares favorably with that of the high-priced machines.

Clamped in the little bench-vise at the left are the two recording funnels. They are connected with the receiving funnels by rubber tubes one and two-thirds meters (five feet) long. The connections must be air-tight. The tubes are made to slip upon the metal stems of the funnels by applying a little talcum powder. Each recording funnel is covered with a rubber diaphragm, upon one radius of which is cemented a small socket. Into this socket the recording lever fits, and into the recording lever the recording point is inserted, as shown. Socket and lever are made of very light imported straws. The recording points are made of two small, flat bits of

kiln-dried pine-wood, united by a wide hinge of rubber dam, as shown in the illustration.* The proximal bit of wood fits into the outer end of the recording lever. The distal piece carries a wire recording point. Levers and points are detachable from one another and from the sockets to facilitate packing; and to prevent their being crushed by heavier objects around, they are separately stored in the smaller of the two containing boxes.

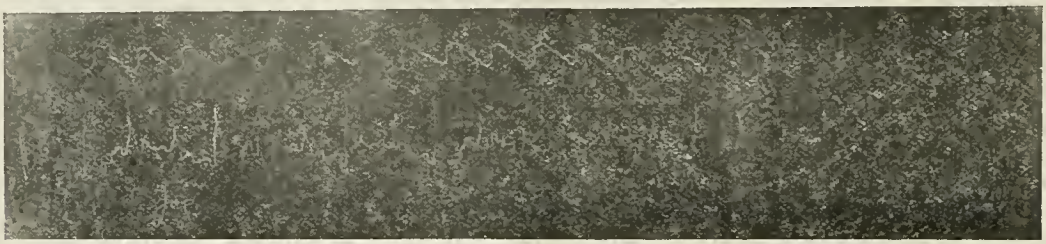

Fig. 6.—A woman with nervous palpitation; jugular shows very high auricular wave, and a respiratory curve.

Fig. 7.—A woman of 33 years with nervous palpitation; carotid above, jugular below.

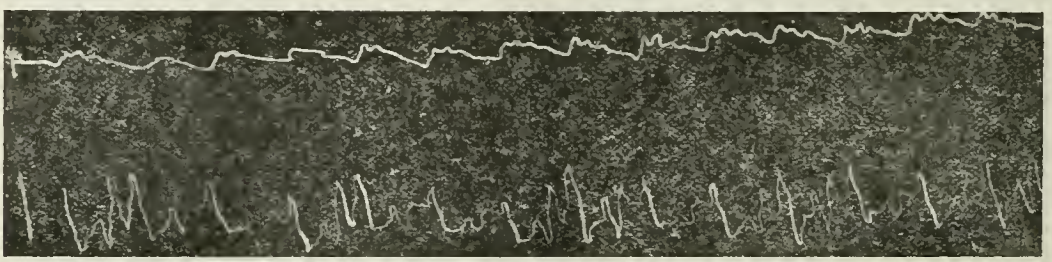

Fig. 8.—Anemic man of 50 years; dropsy to knees; albumin; heart negative, except for bradycardia; carotid is a bisferiens; jugular below shows an auricular type of pulse with four crests and sometimes a slight carotid undulation besides, extra wave probably a "diastolic" or *h* wave of English writers.

The drum mechanism on the right consists of a clock laid on its face, and a wooden cylinder. The clockwork is made to move at three times its regular rate, and the arbor of the minute wheel is produced through the back of the case, and there fits into a metallic socket on the bottom of the cylinder. The cylinder has three pins placed vertically along one line of its convex surface, and to these pins the slip of smoked paper is fixed. The cylinder is packed separately, being easily detached from its shaft. It is 20 cm. in circumference, and makes a complete revolution in twenty seconds, so that on the slip one centimeter is equal to one second, and one millimeter is equal to one-tenth of a second. The cylinder turns for ten hours without stopping, when the clock is fully wound up. The movement seems to be remarkably uniform as far as I have been able to judge of it by ordinary standards. It is set going and stopped simply by touching the top with the finger.

The box is of wood, about half the size of a shoe-box. With its contents it weighs 2¾ pounds and packs readily into a small handbag.

A small, flat pasteboard box, shown in front of the larger box, not only protects the fragile levers and points, as stated, but also carries the supply of paper slips. These may be of any kind of smooth well-finished white paper and should measure 5 x 21 cm. or thereabouts. I smoke them just before using, and I find a bit of cheap plumber's candle perfectly

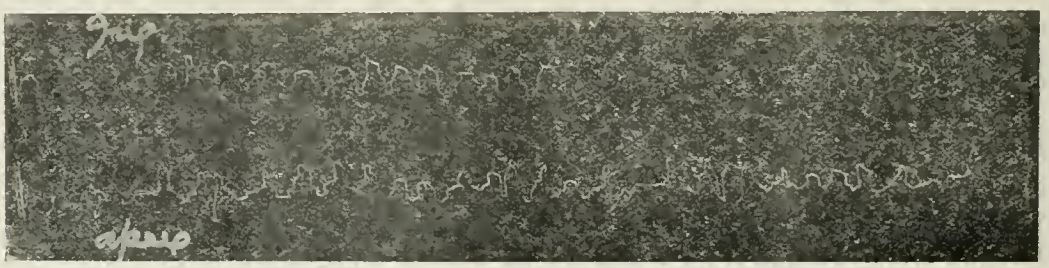

Fig. 9.—Man of 42 years, advanced valvular disease; nodal rhythm; jugular above, apex bent below.

*This arrangement I had devised for myself before I found it described in Dr. E. W. Scripture's interesting work on Speech Curves.

satisfactory. It takes three or four minutes to smoke half a dozen papers. Each slip should be allowed to cool now and then, and then be again

Fig. 10.—Man of 37 years; mitral regurgitation; extrasystoles; venous pulse (below) very imperfect.

applied to the flame. When the tracing is completed the slip is run through a little pan or saucer of alcoholic shellac solution and laid on blotting paper to

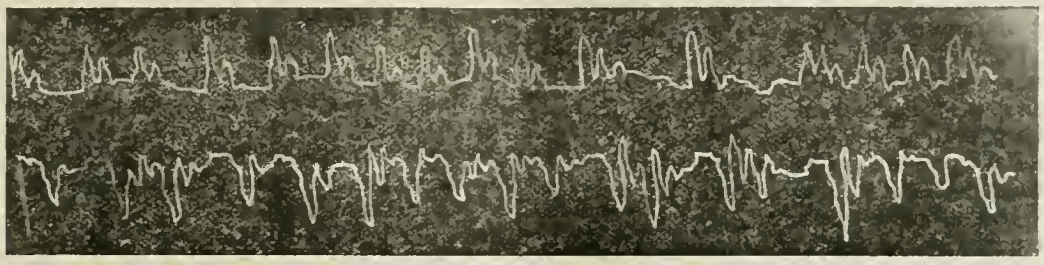

Fig. 11.—Man of 35 years; advanced complicated rheumatic valve-lesion; nodal rhythm; venous pulse (below) shows at right two waves not appearing in carotid (above).

dry. White shellac is much better than yellow.

The vise may be made large enough to hold three or four recording funnels, but the increased difficulties would not be counterbalanced by the relatively small advantages.

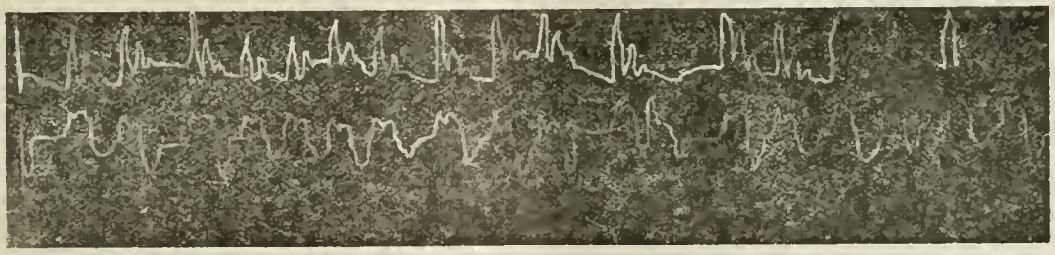

Fig. 12.—Same patient another day; same phenomenon.

Fairly representative tracings made by my instrument are shown in the accompanying figures. Each is explained in the subscribed legend and requires no further comment.

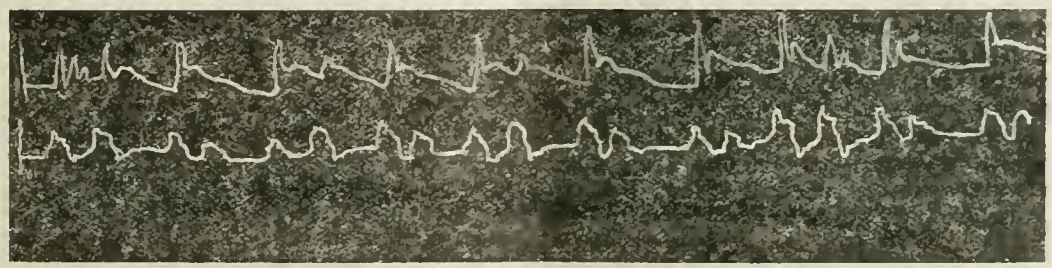

Fig. 13.—Same patient a month later after thorough treatment with digitalis; greatly improved general condition, ventricular bigeminy in the cardiogram (below) not appearing in the carotid (above).

To operate the machine, the patient is placed on a table or bed on his back. If it is wished to take a simultaneous tracing of the carotid artery and jugular vein, for example, the carotid funnel is strapped to the left side of the neck as described and the jugular funnel is held steadily over the right internal jugular vein. The receiving funnels are screwed vertically, side by side, one diaphragm one or two centimeters higher than the other, in the vise, the vise being made to fit any ordinary table or desk-flap. By compressing the rubber tubes the levers and points are adjusted so that the axis of each lever is horizontal, and by twisting the funnels and telescoping the straws the writing points are disposed so that their tips are exactly in one vertical line. The drum is approached to the writing points so that they impinge lightly upon the smoked paper. The clock may rest on a block of wood, or a book, if not high enough otherwise. When the levers have moved a few times upon the motionless drum, so as to indicate the alignment exactly, the drum is set in motion and allowed to run till one revolution has been completed. It is then quickly moved away, and the slip is taken off and dipped in shellac. The tracing is inverted, but this is no disadvantage, as the slip needs only to be turned around to make the readings intelligible.

36 East Fifty-third Street.

THE CARE AND COMMITMENT OF INSANE PERSONS BY HEALTH OFFICERS.*

By WILLIAM L. RUSSELL, M.D.,

NEW YORK.

MEDICAL INSPECTOR FOR THE STATE COMMISSION IN LUNACY.

A PROPOSAL to bring mental diseases within the field of work of the health officer may strike some as novel and possibly not altogether appropriate. The sphere of the health officer is, however, being steadily enlarged so as to embrace more and more of whatever relates to the public health. Why not, therefore, mental diseases? The conditions included under the general term "insanity" are now recognized to be of a character which must receive the attention of physicians, and the cases are regarded as proper subjects for medical care and treatment. These conditions resemble infectious diseases to the extent of requiring official action for the public good and isolation of the cases. They are, too, in a great many instances, the outcome of avoidable causes, some of which are in the nature of infections. The prevalence of mental disease in a community and the public care and commitment of the cases is fundamentally not a question of poverty nor of crime. It is a health question.

The medical view of insanity was not always so generally accepted as it is to-day, and the history of the care of the insane is a story of a long, hard struggle for its application in the practical methods of dealing with the cases. The struggle has been carried on by comparatively few physicians and philanthropists, arrayed against whom have been the forces of superstition, ignorance, and selfishness, and the inertia of generally accepted views and customs. An epoch in the struggle in this State is marked by the passage of the State Care Act in 1890. This act provides that all poor and indigent insane persons in need of institutional care shall be cared for in State institutions, that private institutions for the insane shall be conducted only under State license, and that the execution of the laws relating to the care of the insane shall be under the direction of a State Commission in Lunacy. One of the most important features of the system of State care which has thus been established is the extent to which the medical view of insanity prevails in its organization and administration. The Commission in Lunacy is presided over by a physician, the superintendents of the State hospitals, and those in charge of the licensed private institutions are physicians. Nurses and sometimes physycians are sent to the various communities to bring the cases to the hospitals, and medical administration prevails throughout the system. More than three hundred physicians are engaged in this work, about two hundred of which are employed by the State. The number of patients attended to annually is about 38,000. State care of the insane is the most extensive organized medical work that the State is engaged in, and as such is something in which the medical profession may feel a just pride and interest.

The State system is, however, organized almost entirely with reference to institutional care and to the larger State questions relating to insanity. The problem of dealing with mental disease in the community and of attending to questions relating to the commitment of individuals remains with the local authorities, and is not attended to according to any uniform system nor always with regard to the medical view of insanity. Notwithstanding its important bearing on intelligent effective treatment of the cases, and on questions relating to prevention, this problem was evidently not fully worked out by the extremely able and farseeing framers of the State Care Act. It should be remembered, however, that State care of the insane is of comparatively recent development in this country. Previous to 1850 only twenty State hospitals were in existence, and the care of the insane was, in most places, a purely local question. At that time large numbers of insane persons were confined in jails and lockups, in crude receptacles connected with almshouses, or, in various degrees of degradation and misery, were kept at home or allowed to roam at large. Eventually, in the more populous communities, the insane were segregated in special institutions connected with almshouses, or, in some instances, under separate medical management; and finally, in 1896, six years after the State Care Act was passed, in this State, the State assumed the full responsibility. Under the earlier methods, the insane person in the community had been a subject for the constable and the poormaster, and the organizers of the system established under the State Care Act were unable to change this entirely. In 1891, the Commission in Lunacy recommended in its annual report to the Legislature that the statute be amended so as to provide for special local officers who should have preliminary charge of insane persons, and to take from the poor authorities the duties of determining the questions which relate to commitment. No change was, however, made. Briefly stated, the statutory duties of the poor authorities relating to the insane are: (1) to see "that all poor and indigent insane persons within their respective municipalities are timely granted the necessary relief conferred by" the statute, (2) to see that those who have sufficient means to support them are "properly and suitably cared for and maintained" by their relatives or guardians, or if not, that they are committed to institutions, and (3) to "take proper measures for the determination of the question of the insanity" of any person apparently insane, who may be arrested by a peace officer for "conducting himself in a manner which in a sane person would be disorderly." These duties relate practically entirely to care and treatment, to the determination of insanity, and to commitment. The problems involved are as purely medical as the care and treatment of the insane in institutions, which by common consent the world over have been entrusted to physicians. In the Borough of Manhattan the duties are attended to by the Trustees of Bellevue and Allied Hospitals, and there and in Brooklyn the work has been fairly well organized under medical management. Elsewhere, throughout the various towns and cities of the State the superintendents and overseers of the poor attend to it. In Albany and in Rochester an effort has been made to provide for temporary hospital care for the cases previous to their commitment, and to have the work attended to under medical management. As a rule, however, the methods employed and the facilities provided, differ little from those of twenty years ago, when the distressing condition of so many insane persons cared for by the poor authorities led to the agitation which resulted in the adoption of State care. The local poor authorities, I am sure, attend to their duties conscientiously and to the best of their ability. They are, however, laboring under

*Read at the ninth annual conference of the Sanitary Officers of the State of New York, November 12, 1909.

the burden of the views and methods which prevailed so long under the old system, of lack of insight into the conditions from which the cases with which they are dealing suffer, and of the economy in expenditures incidental to their principal work, which is the relief of poverty. The medical needs of the cases are consequently frequently ignored, and in emergencies the only resource thought of apparently, for men and women alike, is the constable and the lockup. To those who see the cases after their admission to the institutions, the extent to which police methods have been employed in dealing with them in the communities seems quite unnecessary and often extremely injurious. This question is discussed in two special reports issued by the Commission in Lunacy, which were the result of an investigation made by a committee which was appointed at a conference of representatives of the State hospitals with the commission. These reports show that even in the Borough of Manhattan in New York City, where the work is in most respects managed well, fifty-five per cent. of the cases obtain hospital care only through police channels. In the Borough of Brooklyn in the same city, on the contrary, where nurses employed by the poor authorities are sent to the homes for many of the cases, the possibility of eliminating the police to a great extent is clearly demonstrated. In the rest of the State it was found that nearly twenty per cent. of the cases received at the State hospitals were found by the nurses who were sent for them, in jails, lockups, and other places intended only for criminals. The conditions to which some of these cases were subjected are described in the reports referred to, and cannot be justified except on the ground that they were the inevitable outcome of an inefficient system for which no remedy had yet been found. The cases were, in most instances, brought to the hospital without much difficulty by one or at most two nurses, and their behavior after admission did not indicate that the severe measures employed were unavoidable. The investigation showed also that a considerable proportion of the cases received directly from homes had there been subjected to gross neglect or illtreatment, often for long periods, sometimes years. Altogether, in the whole State, exclusive of Greater New York, about 35 per cent. of the cases admitted to the State hospitals in a year, or about 1000 insane persons, had, previous to their admission, been confined in jails or lockups, or subjected to gross neglect or illtreatment at home. Looked at with reference to disease and its proper treatment, a system that fails to protect such a large proportion of the cases from injurious experiences can hardly be considered free from defects.

With a view to remedying these defects it is proposed now to take a step toward placing mental disease in the community on the same footing as other diseases which require official action, and to transfer from the poor authorities to the health officers the statutory duties which have been briefly outlined. These duties are practically of a medical character and will be better attended to by physicians. In New York City the work is already so well organized under hospital auspices that no change is contemplated there. In other parts of the State the health officers are the only medical officials available, and to utilize them seems more feasible than to attempt to establish a new position as was recommended by the Commission in Lunacy in 1891. In Rochester, and possibly in other cities where the Health Bureau attends to the needs of the sick poor, the health officers already frequently look after insane cases. If the duties and responsibilities relating to the care and commitment of insane persons are transferred to the health officers, it will, I believe, assist in establishing in the minds of people in general that the cases are suffering from illnesses which require the attention of physicians and nurses, and which are likely to be aggravated by the methods of the constable and the poormaster. The tendency of the friends of an insane person is to look to physicans and to medical officials for aid rather than to the poor authorities. Recently in one of the large cities a number of citizens appealed to the health department on account of the presence of several insane persons in a house in the neighborhood, and the health officer took the matter up and dealt with it as he would have with any other health question. In another city a letter was received by the board of managers of the State hospital located there, from the local health officer, who asked their cooperation to secure better facilities for the temporary care of insane persons in the city. The health officer would, when consulted, be more likely than the overseer of the poor to appreciate the nature of the case and to act promptly. In the care and management of the cases he would be more likely to employ nurses and attendants than the police. This would doubtless result in earlier treatment, and conditions which lead now to severe measures in some instances would often be anticipated. Advantage would probably be more frequently taken of the provisions made by statute for admission to the State hospitals by means of the emergency commitment and by voluntary application. Consultations with the hospital physicians and the employment of State hospital nurses when necessary could no doubt be arranged for under proper conditions. I can promise for the department that an earnest effort to be helpful would be made.

Better cooperation between State and local authorities with special reference to the medical needs of the cases would do much to overcome the present difficulties. Local hospital provision is also essential. This would no doubt be more keenly realized by medical officials than it is by the poor authorities and a strong effort would likely be made to obtain it. In this the aid of the local medical profession could be counted on. A splendid example of what can be accomplished was shown in Albany when, ten years ago, according to Dr. Mosher, seven physicians succeeded in securing from the county board of supervisors the establishment of the psychopathic ward at the Albany hospital. The Commission in Lunacy could also be confidently expected to aid in any way in its power, and it may be possible to obtain legislation that will enable the Commission to be even more helpful than it can be at present. Better hospital provision for mental cases in the communities is much needed, not only for the better care of cases whose commitment to the State hospitals is contemplated, but also for the better treatment of the psychoneuroses, of intoxications, of infection deliria, and of other conditions out of which insanity may develop. The problem of insanity is by no means solved by the segregation of the cases in large State institutions. A more widespread intelligent interest is needed. Those who deal with the cases in the earlier stages need to have a better insight into the nature of their disorders and into the conditions from which they arise than is at present the case. This would be a step toward more

efficient treatment and cure, and should eventually assist in increasing activity and interest in preventive measures. Not less than 40 per cent. of the male admissions to the institutions for the insane are due directly to alcohol, drugs, syphilis, and the acute infectious diseases, and the better understanding of the nature of the conditions from which the cases suffer, which has been made possible by the advance in clinical psychiatry, is opening up the way toward preventive measures more and more clearly. State care has already done much for clinical psychiatry. The proposed plan for extending the application of the medical view of insanity to the official methods of dealing with insane persons in the communities is in a measure an extension of State care. The health officers are to some extent State officials. They are, more or less, organized under the leadership of the State Commissioner of Health. The foundation is thus provided for building up on a medical basis, under State auspices, a system of dealing with the whole problem of mental diseases in a more efficient way than has ever been undertaken before. An opportunity for an extremely useful and promising field of work is offered to the health officers.

A bill has been prepared to provide for the legislation needed. In this bill ample provision has been made for compensating the health officers for the extra work and responsibility required of them, and the wish of those interested in the bill is to act in harmony with the State Commissioner of Health in safeguarding the interests of all concerned and of the other important work which the health officers are engaged in.

ADULT SYPHILIS OF THE LUNG:

WITH A CASE REPORT.

By HENRY HUBBARD PELTON, A.M., M.D.,

NEW YORK.

ADJUNCT ASSISTANT ATTENDING PHYSICIAN TO BELLEVUE HOSPITAL; CHIEF OF MEDICAL CLINIC, PRESBYTERIAN HOSPITAL, OUT-PATIENT DEPARTMENT.

It seems quite probable that syphilitic lesions of the lung in adults occur much more frequently than they are diagnosticated, the chief reason why such processes are not demonstrated during life being the resemblance of their physical signs to those of certain types of pulmonary tuberculosis.

Bériel[1] states that acquired lues of the adult lung is common, but the specific nature of the affection must be deduced from its occurrence with syphilitic lesions elsewhere in the body. He considers that two types may be described. (1) Catarrhal pneumonia or the desquamative bronchopneumonia of Homolle. This is characterized by the presence in the alveolus of a considerable amount of large cellular elements, more or less changed. The liquid exudate, which is at times present, gives to these lesions, on macroscopic examination, a peculiar appearance which Hiller has termed gelatinous pneumonia. (2) The so-called interstitial pneumonia, of which the principal feature is the increase in thickness of the interstitial framework of the lung with infiltration of its whole tissue. Of these two types the second, with its varieties, seems to be more directly due to syphilitic infection, and it represents the true syphilitic pneumonia.

Such pneumonic processes as the above may result in a cicatricial sclerosis which may occur in bands, *en bloc*, or at the nucleus of gummata (these, according to Virchow, result from connective tissue proliferation) simulating at first, in their growth, granulation tissue. The later development of gummatous tumors may take place in one of two ways. Either the cellular formation prevails, the intercellular substance rapidly softening and becoming gelatinous, mucoid, or fluid, and the tumor degenerates, becomes puriform, opens outward, and ulcerates, or, on the other hand, the cellular elements being not very abundant, the intercellular substance increases, the cells preserving the fusiform or star-shaped character of connective tissue cells or assuming the round shape of those of granulation tissue. Later the cells become fatty and the dry, yellow node of visceral syphilis is formed.

Keyes[2] describes the lesions of pulmonary lues in adults as being either soft or hard, according to

Fig. 1.—Showing the dilated veins in the chest and abdomen.

their density; this density depending upon the age of the process and upon the transformation of the exudate into organized tissue. This sclerosis is the usual lesion of acquired syphilis of the lung. It is likely to be of irregular distribution and is more common in the lower than in the upper lobes and in the right than in the left lung. The sclerotic tissue is hard, grayish white, or blackish, and very retractile; it may occur in bands radiating from a central point or in nodular masses which are often beneath the pleura; fibrous peribronchitis may be present. With the luetic interstitial changes there are usually bronchiectatic cavities of various shapes and sizes. Often such a cavity is the chief lesion and may be of considerable size; it may contain pus or its walls may be necrotic and gangrenous, like those of tuberculous cavities. Keyes also states

that, while mixed infection with the bacillus tuberculosis is said to be common, it is likely that many of the classical instances of pulmonary syphilis are merely irregular tuberculous processes and that the frequency of the coexistence of the two affections has been overestimated although a few authentic

Fig. 2.—Skiagram of the thorax of T. B.

cases have been recorded. He quotes Tripier and Bériel as holding that most instances of bronchiectasis are due to unsuspected syphilis of the lung.

With regard to the existence of simple connective tissue hypertrophy of the pulmonary framework Virchow maintains[3] that there may occur simple irritative affections of the lungs of luetic origin which never become gummatous, and he is inclined to regard certain fibrous forms of pleuritis, of pneumonia, and of peribronchitis as analogous to the chronic syphilitic inflammations of the liver and other viscera.

Rollet[4] has demonstrated that pulmonary syphiloma may appear not only in nodular masses of irregular size and differing shape, but also as a diffuse infiltration, which, alone or in connection with nodules, may extend over a pulmonary lobe.

Schnitzler[5] describes diffuse syphilitic disease of the lungs in which the organ is generally of firmer consistency, of greater weight, and of more uniform surface. The infiltration extends over one or both lungs or over only a part of them. The infiltrated parts are, as a rule, entirely airless, grayish red or grayish yellow, smooth, homogeneous, with a scanty turbid juice. The bronchi are usually of normal caliber and are filled with much purulent mucous and little air. The pathology of this type of pulmonary syphilis seems to coincide with the condition in the case reported subsequently as evidenced by the physical signs and radiographic picture.

With regard to the presence of the *Spirocheta pallida* in the lesions of acquired syphilis of the lung Levaditi and Roche state that, in contradistinction to the lesions of hereditary syphilis, the spirocheta is rarely found in the lesions of acquired lues. It has been found, in specific aortitis, in the wall of the aorta, in the suprarenal capsules, and possibly in hepatic gummata.

Concerning the association of syphilis and tuberculosis of the lung Mauriac (see Bériel[1]) considers that in the lungs, as elsewhere, the two affections remain independent and do not affect one another in any marked degree despite the analogy and strong resemblance of their lesions. Neither do they combine to form hybrid products endowed with power to transmit themselves. Their combined presence is merely juxtaposition and does not create mixed forms of tuberculosyphilitic pneumopathy. Their association occurs in various types: (1) With manifest and extensive syphilitic lesions there may be histologic changes referable to tuberculosis, but the lesions and symptoms are not modified by the association. (2) Inversely, in tuberculous patients who are also syphilitic there may be, in the neighborhood of the bacillary lesions, histologic features of luetic nature. (3) In apposition to the preceding types, which are frequent, is the type in which marked tuberculous and syphilitic lesions coexist. Here the clinical aspect is such that the diagnosis is almost impossible; the luetic affection is not recognized and the tuberculous process alone is diagnosticated.

Fournier[5] views the association of tuberculosis and syphilis from three clinical aspects: (1) When syphilis is engrafted upon a proved case of tuberculosis the course of the latter becomes more rapid and severe. (2) When the tuberculous infection appears during the early stages of lues. Here also the prognosis is grave and the course of the tuberculous infection is almost always rapid (Jacquinet). (3) When tuberculosis is engrafted upon an old syphilitic process (Landouzy) the disease assumes a form of fibrosis of tardy, sluggish, afebrile evolution. The bacillus appears to live as a parasite upon the surface of the syphilitic cavities in the lung without causing ulceration. The patient may sur-

Fig. 3.—Fundus of the eye of T. B., showing disseminated syphilitic choroiditis.

vive for a considerable period and may appear to be doing well.

With regard to the differentiation of tuberculosis and syphilis of the lung the same author gives the following points: (1) Absence of tubercle bacilli in the sputum is a negative point of great importance. Repeated examination is an essential as also

are continued negative results. Syphilis is probable in the persistent absence of bacilli, cancer cells, or evidence of hydatid disease. (2) Character of the local lesion. Syphilis is unilateral, circumscribed, and has no predilection for the apices of the lungs. It must be remembered, in this connection, that tuberculosis also may begin in one lung only and that it is possible for lues to affect both lungs simultaneously. Pulmonary syphilis is usually circumscribed while tuberculosis is more likely to be disseminated. Tuberculosis usually begins at an apex. Syphilis is less discriminating; it may occur in the lower, middle, or upper lobe. Its preference is for the middle of the organ in the neighborhood of the hilum. (3) General symptoms: tuberculosis affects the constitutional condition and causes the well-known train of symptoms; emaciation, weakness, anorexia, dyspepsia, diarrhea, rise of temperature, etc. Syphilis does not influence the appetite or the nutrition, as a rule; if the general health is impaired such impairment is of slow and gradual evolution. (4) The course of tuberculosis is likely to be rapid while that of syphilis is tardy.

According to Bériel, for the diagnosis of pulmonary syphilis are necessary: (1) Assurance of a previous leutic infection. (2) Presence of other visceral lesions of evident specific character. (3) The certainty that the lesions are not due to infection of other type—especially tuberculosis.

To discuss these three considerations in order: the history, if negative, is of little importance. Syphilitic subjects may present lesions of diverse nature and characteristic manifestations may be absent in patients plainly luetic. A denial of specific disease should never be considered to exclude pulmonary syphilis.

The presence of other specific lesions in various viscera, such as hepatic gummata, laryngeal changes (which are frequent in pulmonary syphilis) aids in the diagnosis. The existence of parasyphilitic alterations, such as spinal tabes, specific aortitis, aneurysm, etc., is also of assistance. Still these lesions and signs of infection may be absent in true lues of the lungs and present in tuberculosis.

Laboratory and other clinical tests made with a view to the elimination of tuberculosis are also insufficient criteria by themselves and likewise have the great disadvantage that, like all negative proofs, they are inconclusive. Absence of bacilli in exudates or sections is no proof of syphilis; negative inoculations do not rule out tuberculosis, and even in positive reports the hypothesis of specific disease cannot be excluded. The presence of the tubercle bacillus is a criterion in favor of tuberculosis but it does not exclude the possible coexistence of syphilis. Successful inoculations also afford an unsatisfactory affirmation for the same reason. Such tests are useful only in that they, when positive, prove the presence of tuberculosis. As stated previously the *Spirocheta pallida* is most unlikely to be found in the lesions of adult syphilis of the lung and the presence or absence of the Wassermann reaction is as unconfirmatory as are the laboratory and other tests for tuberculosis.

Case Report.—T. B., an intelligent man, 46 years of age, a cook by trade, came under the writer's notice in September, 1908. He was first seen at the tuberculosis dispensary of Bellevue Hospital and was immediately admitted to the ward.

Family History.—Negative as regards syphilis and tuberculosis.

Previous History.—Measles and whooping cough in childhood; chancre fourteen years ago, followed by the usual secondaries on skin and mucous membranes; irregular treatment for two years. Gonorrhea nine years ago. Served in the Spanish war and had malaria and (probably) typhoid fever during his service. About seven years ago he noticed a swollen vein on the right side of the neck and a feeling of dizziness on stooping. This swelling disappeared and a dilatation of the veins showed itself just inside the front of the right shoulder; soon the veins of the right arm became swollen down as far as the elbow and the superficial veins of the chest and abdomen began to enlarge on the right side. Three years ago the veins of the left arm and of the left side of the chest and abdomen also became swollen and prominent. About one year ago he suffered from what was apparently an attack of acute nephritis but recovered. He had been accustomed to indulge in alcohol to a considerable degree.

Present History: About four years ago the patient began to lose flesh and strength and developed a cough which has persisted ever since. Three months later he expectorated some blood. Blood has appeared in his sputum (which has been profuse and mucopurulent) from time to time ever since. There has been up to this time no sudden expectoration of a considerable amount of matter followed by a diminuation of the cough and expectoration. He has had no night sweats, feverish, or chilly feelings. He has been treated at intervals for tuberculosis of the lungs, but says that his physicians have never been sure of the diagnosis. In November, 1907, he entered a sanatorium in Texas where he remained for six months. While there he received numerous hypodermatic injections of tuberculin for the purpose of diagnosis, but says there was never any positive reaction. His sputum has been examined many times but tubercle bacilli have never been found. While at the sanatorium he improved, but began to suffer from pain in the left upper jaw in the region of the canine tooth. This pain later spread so as to affect the entire left side of his face and head and is still present. The pain is severe, deep, and boring in character with occasional sharp, shooting pains in the left eye and ear. About a month ago he noticed that he could not move the left eye outward. He complains chiefly of cough, with thick, yellowish, mucopurulent sputum which is sometimes bloody, general weakness, pain in the left side of head, and poor eyesight.

Physical Examination: The patient is poorly nourished (weight 114 lbs.), his face is red and congested and is somewhat more full on the left side. There is slight left exophthalmos and paralysis of the external rectus of the left eye. The pupils are normal; there is marked clubbing of the fingers. The superficial veins of the arms are dilated. The radial arteries are moderately thickened. The thorax is symmetrical, elongated and barrel-shaped; the costal margins are everted. The superficial veins are enlarged, tortuous, and distended, more especially on the right side. (See Fig. 1.) Heart: The apex impulse is not definitely localized; the cardiac dullness is obscured; the apex beat is heard loudest over the sternum just above the ensiform cartilage. The heart action is regular, there are no murmurs; the aortic second sound is accentuated. Lungs: There is diminished expansion of the right lung; the vocal

fremitus over the entire right lung is increased except at the base behind, where it is normal. The note upon percussion is dull in front as far as the third rib, it is flat below this point; behind the note is dull to the midscapular region and flat below this point. The breathing over back and front is bronchovesicular; the voice is bronchial, especially so over the lower lobe. On admission there were numerous fine rales over both back and front; later these disappeared. The left lung gives the usual signs of compensatory emphysema with the addition of slight dulness at the apex and a few fine rales here and at the base behind. An *x*-ray photograph of the thorax was taken (see Fig. 2.) The abdomen is scaphoid in shape; the superficial veins are dilated and tortuous. The liver is palpable about one inch below the costal margin. The reflexes are normal. Laryngoscopic examination reveals no abnormality. Ophthalmoscopic examination shows the presence of a choroiditis and retinitis of evident syphilitic nature. (See Fig. 3.)

The patient's sputum was carefully examined for the presence of the tubercle bacillus, always with a negative result. Inoculation tests were also made, the inoculated guinea-pig remaining alive and healthy after six weeks had elapsed. The opthalmic test (0.025 cc. of ½ per cent. tuberculin) was employed and gave a doubtful positive reaction. This measure was taken before the choroiditis has been demonstrated, otherwise it probably would not have been used. It caused only a slight reddening of the conjunctiva. The cutaneous reaction (50 per cent. tuberculin) produced a moderately positive result. Injections of 1.5 mg. and 4.5 mg. of tuberculin caused no diagnostic reaction, but following an injection of 9 mg. the patient's temperature rose to 101.5 deg. Fahr.; there were, however, no marked constitutional symptoms. Exploration of the pleural cavity did not reveal the presence of fluid.

The Wassermann reaction was not employed because it seemed unnecessary. Had it been positive nothing would have been proven concerning the pulmonary condition, and had it been negative one would have hesitated to rule out syphilis on account of the history, the characteristic ophthalmic lesion, and the prompt improvement of the patient when put upon antiluetic treatment.

During the twenty-six days that the patient remained in the hospital his temperature was never above 99.5 deg. Fahr., except following the injection of tuberculin mentioned previously, and for the most part it was slightly below normal. The weight rapidly increased to 132 lbs. and the patient gained markedly in strength. Under massive doses of potassium iodide and small doses of mercury bichloride the pain in the face disappeared and the visual disorder became greatly ameliorated.

The patient was discharged at his own request since he wished to resume work. He was seen a few days later at the Presbyterian Hospital Out Patient Department, where the accompanying *x*-ray photograph was taken; at this time he felt in good condition, complaining only of cough with occasional bloody expectoration. The physical signs were practically as when first seen except that the rales at the apex of the left lung had disappeared. He was advised to continue taking potassium iodide. Since this time he has not been heard from, his work having taken him out of the city.

I have recently learned that the patient spent several weeks at the N. Y. Health Department's Sanatorium for Tuberculosis at Otisville, N. Y., in the summer of 1909. During this time his sputum was examined three times for tubercle bacilli with negative results, and Dr. E. S. McSweeny, the physician in charge of the institution, has informed me that he considered the case an instance of pulmonary syphilis.

It would seem to the writer that this is, very probably, an instance of acquired syphilis of the lung; whether there has, rather recently, been engrafted upon the luetic process an infection with tuberculosis is debatable. The positive reaction to the tuberculin injection appears to point toward that possibility. At any rate a consideration of the case, if it will show nothing else, will demonstrate the difficulties with which the diagnosis of pulmonary lues *intra vitam* is fraught.

The writer wishes to express his thanks to Drs. F. J. Parker, A. M. Pappenheimer, and I. O. Woodruff, who have materially assisted him in the preparation of this report.

ETIOLOGY AND UNDERLYING CAUSES OF PULMONARY TUBERCULOSIS.*

By WALTER SANDS MILLS, A.B., M.D.,

NEW YORK.

PROFESSOR OF PRACTICE AND CHIEF OF TUBERCULOSIS CLINIC, NEW YORK HOMEOPATHIC MEDICAL COLLEGE AND FLOWER HOSPITAL; VISITING PHYSICIAN, TUBERCULOSIS INFIRMARY, METROPOLITAN HOSPITAL, DEPARTMENT OF PUBLIC CHARITIES.

I HAVE selected this topic because in the last few years there has been a vast overrating of one side of the question to the exclusion of other sides quite as important in my opinion. I refer to the popular belief that all one has to do to contract tuberculosis is to inhale a few tubercle bacilli. That as the bacilli are thrown off in the sputa, each consumptive is a source of danger to others and should therefore be shunned. This idea of the contagiousness of pulmonary tuberculosis has been instilled into the public mind, in season and out of season, during the last four or five years to such an extent that phthisiophobia has become a common disease, not only with laymen, but with many physicians. In consequence, in many communities the consumptive has become a pariah, shunned like a pestilence. The United States Government refuses admission to consumptive immigrants. Colorado and Texas, I believe, refuse to admit consumptives from other states. Oklahoma refuses to admit them and has put a ban on consumptive physicians.

At the meeting of the Homeopathic Medical Society of the State of New York in September, one of the members reported that it was very difficult for a known consumptive to obtain lodgings or food in Texas. He had just returned from a tour of the state with a patient affected with tuberculosis. Another physician told the pathetic story of a nine-year-old girl in his village whose father had tuberculosis. None of the other children of the

*Read before the Homeopathic Medical Society of Connecticut, October 19, 1909.

place would associate with her. They were afraid of her, although the child herself was perfectly well.

Such things are wrong, all wrong. It is a blot on our civilization that they should be. Many of the present inhabitants of Texas and Colorado and Oklahoma are persons who went there to live in the beginning because they were consumptives, and who have been cured by the health-giving air of those places. A list of the best known workers in tuberculosis, I mean physicians who have become famous as experts in the study and cure of the disease, men with whose names you are all familiar, have been many of them tuberculous. I, myself, while secretary of this society, was taken ill with tuberculosis and sent west to die of it in 1896.

It is estimated that one-seventh of the deaths in the civilized world are due to tuberculosis. It is also estimated that in one-third of all bodies examined post mortem there are found tuberculosis lesions in the lungs. In other words, three out of every twenty-one deaths are due to tuberculosis, whereas seven bodies out of twenty-one show tuberculous lesions. We know that tubercle bacilli are coughed out in the sputa of persons ill with tuberculosis and disseminated through the atmosphere. The germs must therefore be omnipresent, they must exist everywhere. If simply breathing them in was all that was necessary to produce the disease, one hundred per cent. of the population would have tuberculosis and all would die of it. We know that seeds scattered broadcast will not grow unless they fall in congenial soil. Disease germs are no exception to this rule. Tubercle bacilli will not grow in every lung. This is shown by the fact that two-thirds of all lungs examined show no evidence of their presence though they must have been breathed in by the million. It is shown still more strongly by the fact that in four out of seven cases attacked the lung has been able to throw them off. Evidently tubercle bacilli require congenial soil in order to flourish.

The fact that the lung is the seat of the lesion led to the belief, once the tubercle bacillus was discovered, that breathing in of the germ caused the disease. Robert Koch is the leader of those who advocate this view. Experiments conducted by many experimenters in recent years, however, show that pulmonary tuberculosis can result from the ingestion of the bacillus. Schroeder and Cotter, of the Agricultural Department at Washington, in 1906 produced pulmonary tuberculosis in animals by feeding them on germ-laden food. Many other experimenters in this country and abroad have shown the same thing. The bacillus in these cases passes from the intestinal tract into the lymphatics and through them into the lung. A number of students of the disease, among whom may be mentioned Calmette, Landouzy, and Ravenal, now believe that this is the ordinary method of infection. They do not deny the possibility of respiratory infection, but believe it to be comparatively rare.

In 1903 von Behring went still further. He insisted that the tubercle bacillus was ingested in the milk during infancy, that it remained dormant in the body for months or years, as the case might be, and then from some cause developed tuberculosis in the victim. His theory did not admit of respiratory infection at all; and it did not admit of ingestion infection later in life, because the large intestine becomes impervious to the transmission of bacilli later in life. Coming from a man of von Behring's standing this theory had a respectful hearing and is not lacking supporters. It has one advantage from a practical standpoint, namely, each and all of us either did or did not imbibe the bacillus in infancy. If we did imbide it then sooner or later tuberculosis may claim us; if we did not, tuberculosis cannot claim us no matter what we do now.

I have mentioned some of the theories as to the mode of entrance of the tubercle bacillus into the body. I wish now to consider the tubercle bacillus itself. The tubercle bacillus is a short rod-like structure that appears in the discharges of a tuberculous subject. It has been found in the urine and the feces as well as in the sputum. Boiling kills it. A heat of 140° Fahr. will kill it after twenty minutes (Rosenau, Schroeder, Smith, and others). Cold has no effect on it. Direct sunlight kills the bacillus in a few hours, diffused light usually in a few days; in one or two cases virulence was retained several months (Koch, Rosenau, Annett, Twitchell, Weinzirl, and many others). Its virulence lasts longer in a dark moist atmosphere than elsewhere. The experiments showing the length of life of the bacillus under varying conditions consisted first of selecting particularly virulent sputa; second, of inoculations into guinea pigs which are extremely susceptible to tuberculosis. Under ordinary conditions bacilli expectorated into the street soon lose their vitality, and probably risk of respiratory infection is slight. In dark rooms the bacilli live longer, but ordinary cleanliness—discharging the bacilli into sputum cups containing antiseptics, or into something that can be immediately destroyed—should prevent the distribution of the germs.

Whatever the mode of infection of tuberculosis may be, whether by inhalation or by ingestion, if all discharged bacilli were properly cared for and promptly destroyed, there would be no danger of infection. But complete destruction of all bacilli is impossible. It is probable that all of us inhale and ingest many millions of them every day. Yet all of us are not sick. Why? Because we are not in condition to develop tuberculosis.

This brings us to the subject of soil. What is it that makes some persons susceptible and others not? This is not known exactly, but a mass of material has been collected regarding supposed predisposing causes.

Neither sex is exempt. In England (Kidd) in 1851-1860, the rate of mortality from tuberculosis was higher among females; in 1901-1905 among males. Hutchings reports that among the insane hospitals in New York State during the past eighteen years there have been 28,106 deaths. Among women 20 per cent. of the deaths were from tuberculosis; among the men 9.5 per cent. Moreover, Hutchings says this preponderance of deaths from this disease among women holds true in insane hospitals throughout the United States. In the State at large 10 per cent. of the total number of deaths are due to tuberculosis.

At the Phipps Institute for the Treatment of Tuberculosis in Philadelphia, of 3,733 cases 58 per cent. were men, 42 per cent. women. At the Tuberculosis Infirmary of the Metropolitan Hospital in New York, figures collated by me show that of 16,122 cases 82 per cent. were men and only 18 per cent. were women.

No age is exempt. Of 9,903 cases at the Tuberculosis Infirmary classified by ten-year periods,

there were under 10 years of age, 20; 11-20 years, 869; 21-30 years, 2,222; 31-40 years, 2,513; 41-50 years, 2,027; 51-60 years, 1,269; 67-70 years, 616; 71-80 years, 345; 81-90 years, 20; 91-100 years, 2. The youngest baby girl was three weeks old, the oldest woman 97 years. The youngest baby boy was eleven months old, the oldest man 92 years. Of the 9,503 cases tabulated 6,762, or 68.3 per cent. were between 21 and 50 years of age, the most strenuous and active period of life. Of 600 women patients 494, or 82 per cent., were between the ages of 16 and 45 years, the child-bearing period.

These figures show that whatever may be the exact mode of infection, the greatest ravages of the disease occur during the time when all the mental and physical energies of the individual are being used to their utmost in the struggle for existence and in the perpetuation of the race. These figures do not mean that tuberculosis is contracted at this time of life, they simply mean that patients break down at this time of life.

This is also the period of greatest social and industrial activity, and occupation seems to have some influence as a predisposing cause. At the Tuberculosis Infirmary of the Metropolitan Hospital, where the patients are charity patients, I found that of the one hundred and thirty different occupations represented by the 16,000 patients, unskilled labor headed the list. There were 2,131 laborers; next in number were 1,140 domestic servants and cooks; third on the list were 601 hotel help and waiters; fourth, 459 tailors and sewing machine operators; fifth, 433 drivers; sixth, 194 clerks. It is probable that long hours, hard work, and bad living conditions had much to do with the physical downfall of these patients. I would like to call special attention to the fact that 1,140 of the total number of patients, more than 7 per cent., were domestic servants. As most of these were women, and as only 18 per cent. of the total number of patients were women, it will be seen that domestic service seems to be one of the important predisposing causes.

At the International Congress of Tuberculosis in 1908, Mr. Frederick L. Hoffman, statistician of the Prudential Insurance Company, presented an interesting series of charts showing the relative mortality from consumption in different dusty trades, according to Prudential experience. In all of the following occupations the mortality from tuberculosis was found to be much above the average rate: namely, grinders, polishers, brass workers, tool makers, jewellers, engravers, printers, compositors, stone workers, marble workers, glass blowers, glass cutters, potters, plasterers, spinners, weavers, furriers and taxidermists, hatters, woolen-mill employees, carpet and rug makers, silk-mill employees, upholsterers, millers, bakers, button makers, leather workers, street cleaners, drivers, letter carriers, motormen. The mortality was greatest among those subject to the more or less continuous inhalation of metallic and mineral dust. Most of these trades pay living wages, some pay very good wages. Moreover, the fact that all were insured showed a high degree of thrift. It is fair to assume, therefore, that the exposure to dust inhalation of itself must by irritating the lining membrane of the air passages be a predisposing influence in the development of tuberculosis.

In 1901 Denison of Colorado stated that we must have something beside the germ to produce tuberculosis, we must have a proper soil. He put forth the theory that breathing devitalized air was an important predisposing factor. Improperly ventilated living and working rooms were responsible for the devitalized air. Unquestionably this is true, and bad air is of importance.

Other predisposing causes are various diseases. Tuberculosis will sometimes graft itself on an unresolved pneumonia. Many of the cases at the Tuberculosis Infirmary have had pneumonia within a few months or years. Kidd, in Allbutt's System of Medicine, says tuberculosis following pneumonia is "infinitely rare." My experience does not agree with his. Measles, grippe, and other infectious diseases have been, and still are, recognized as predisposing to tuberculosis. There is some merit, however, in the contention of E. P. Copeland, of Washington, that as nearly every one at some time or other suffers from these diseases, the role they play in predisposing towards tuberculosis is not of much importance.

Traumatism is said sometimes to be the beginning of tuberculosis. I have met with but one case that seemed indisputable. A woman at the Tuberculosis Infirmary dated the beginning of her illness from a kick in the chest which was followed by pulmonary hemorrhage.

Some years ago Rokitansky advanced the theory that certain valvular lesions of the heart, by producing a stasis of blood in the lungs, inhibited the development of tuberculosis. Other observers have not found the facts to be quite like that. Many cases of valvular lesion and of tuberculosis exist in the same patient. A search in one of my wards on a given day showed seven cases of mitral disease, one of aortic disease, and four abnormal cases that were doubtful as to the exact pathological condition, a total of twelve out of forty-five. This represents a morbidity of 26 per cent. In these cases the diagnosis was clinical. It was certain in eight cases, or 17 per cent. The third annual report of Phipps Institute gives a record of 19 per cent. of valvular lesions from two hundred autopsies. The fourth annual report gives a record of 6 per cent. valvular lesions out of a subsequent series of sixty cases examined post mortem.

Among women, many date their illness from pregnancy and childbirth. From my observation I believe that pregnancy is a dangerous condition for a tuberculous woman. It seems to hasten the progress of the disease.

There is one more factor to be considered—heredity. A few years ago tuberculosis was supposed to be hereditary. With the advent of the germ theory, heredity has dropped into the background. The tubercle bacillus has been demonstrated in the spermatic fluid of the male (Rosenberger, Walker, and others); it has been demonstrated in the placenta (Warthin and others). It is without doubt, therefore, that in certain rare cases it may be passed direct from parents to offspring. Those who still believe in hereditary influence believe that the organism inherits a weakened resistance, rather than that the disease itself is directly transmitted. Of late years it has been claimed that children of tuberculous parents exhibit a greater resistance to the disease than others. This is explained on the theory of immunization through the parent (Flick, King).

If cases occur in the same household it is just as probably due to living under the same adverse conditions, as to either infection or heredity. The whole subject requires much further investigation.

Tuberculosis is found clinically and at the postmortem in so large a percentage of children, and healed tuberculous lesions are found so often postmortem in older subjects, that the belief is becoming prevalent that the majority of cases become infected very early in life; that the disease remains latent a longer or shorter time, only to develop under some adverse conditions. Any cause which tends to lower the vitality tends to make the individual more susceptible to the development of tuberculosis. The presence of healed lesions in older subjects proves that the disease can be thrown off.

The way to prevent tuberculosis is to throw every possible protecting influence around the infant to prevent possible infection and to keep the vitality at its highest state of efficiency at all times.

SITUS VISCERUM INVERSUS TOTALIS

By LEWIS J. POLLOCK, M.D., Senior Physician,
AND
EARL B. JEWELL, M.D., Assistant Physician,
COOK COUNTY INSTITUTIONS,
DUNNING, ILL.

The very interesting condition of situs viscerum inversus has always excited a great amount of interest, both from the standpoint of its rarity and the problems it offers to the embryologist.

The first case in literature was reported by Petrus Servius in 1643, Grueber, in a collection of 78 cases published in 1863, analyzed them as follows: Of 78 cases of situs viscerum inversus 70 were complete, of these 49 occurred in males, 19 in females, 10 were not noted; up to 1895 there were collected by A. Pic. 195 cases. Since that time we find that there have been published 128 articles upon this condition, from the reports that were accessible we find in a collection of 78 cases the following facts:

Sex: Males 44, females 11, 15 not reported.

Age: Under one year, 11 cases; 1 to 10 years, 5 cases; 10 to 30 years, 25 cases; 30 to 60 years, 16 cases; over 60 years, 3 cases; 10 not reported.

Fifty-six cases were diagnosed ante mortem; in 14 the diagnosis was made post mortem. A postmortem examination made in 22 cases.

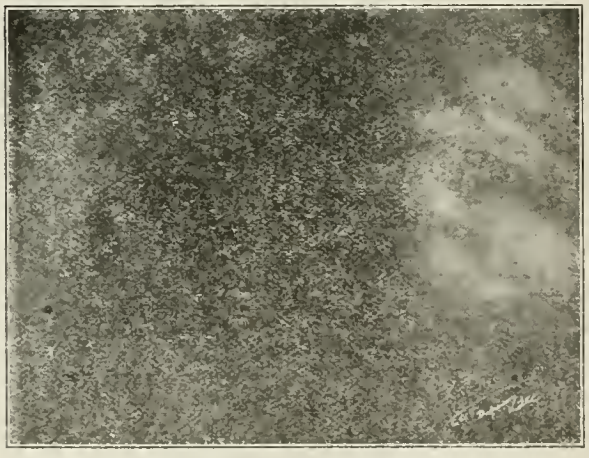

Fig. 1.—Skiagram of the thorax taken from in front, showing the shadow of the heart on the right side.

The case we wish to report occurred in a woman age 44, admitted to this institution suffering from dementia paralytica. A diagnosis of situs viscerum inversus was made by Dr. Clara Dunn, who kindly referred to case to us.

The examination at the time of admission shows a woman in good physical condition.

Chest. Inspection: Chest is large and oval with bulging over the left side, symmetrical thoracic respiration of moderate excursion.

Lungs. Right is bounded anteriorly at its lower

Fig. 2.—Viscera in situ: RL, right lung; LL, left lung, Pc, pericardium; G, gall-bladder; CC, caput coli; B, bladder.

border by the third rib at the midclavicular line; the lower lobe is interrupted by an area of dullness corresponding to the heart outline below. Left extends to the upper border of the sixth rib anteriorly, posteriorly both lungs extend to the level of the second dorsal vertebra. There are no areas of dullness in either lung. Auscultation is negative.

Heart. The right border extends in a line from a point cutting the third rib at the midclavicular line to the apex one finger outside of the right nipple. The left border corresponds to the mid-sternal line. The apex is in the fifth interspace one finger outside the right nipple. Sounds clear with no murmurs.

Abdomen. Palpation shows the lower border of the liver to be two fingers below the costal margin on the left side. Spleen not palpable. The left kidney is felt floating three fingers below the costal margin and freely movable. Percussion shows the liver extending from the sixth rib above to two fingers below the costal margin on the left side. There is an obliteration of tympany over the usual side of Traube's semilunar space with a corresponding area of tympany over the right side. Neurological examination shows dementia paralytica.

The patient died of sinus thrombosis on March 23, 1909. The postmortem findings were as follows:

Lungs. Are transposed in position, the right has two lobes, the left three. The right bronchus is longer, lower and of smaller caliber than the left. The right pulmonary artery is above the right bronchus, crossing it anteriorly before it enters the

lung; the left pulmonary artery lies below the left bronchus.

Heart. Position: The base is directed upward, backward, and to the left. The apex downward, forward, and to the right. The right border extends from the third right costal cartilage, one inch from

FIG. 3.—Thoracic viscera: RL, right lung; LL, left lung; X, apex of heart; PA, pulmonary artery; A, aorta; 1, right subclavian; 2, right common carotid artery; 3, Innominate artery; 3′, left common carotid; 3″, left subclavian.

the sternum, descending obliquely, with its convexity to the right, to the apex. The left border lies behind the third to sixth rib on the left. The chambers are transposed completely; the right auricle receiving the pulmonary veins, the left auricle receiving the superior and inferior vena cava; the right ventricle having a thicker wall, forming the posterior portion of the apex, giving off the aorta; and the left ventricle, forming the anterior portion of the apex, lying on the diaphragm, being thin walled, and giving off the pulmonary artery. The tricuspid valve is on the left and the mitral on the right side.

Vessels. The aorta commences at the base of the right ventricle, ascends with an inclination to the left to the level of the second costal cartilage, then extends backward to the right side of the fourth dorsal vertebra. Of the three branches of the arch of the aorta, the innominate arises from its convexity near its left extremity, the right common carotid from the arch, the right subclavian from the arch, the left common carotid from the innominate, the left subclavian from the innominate. The pulmonary artery arises from the anterior and right angle of the base of the left ventricle runs upward and backward toward the concavity of the aorta.

Liver. The main mass lies in the left hypochondriac region, the left lobe is the larger of the two, and is in relation on its inferior surface with the hepatic flexure at the junction of the ascending and transverse colon. The right is larger than is usually the case with the left lobe normally, and is in relation on its inferior surface with the stomach. The quadrate lobe is to the right of the gall-bladder, the Spigelian lobe is to the right of the caval fissure, the fossa of the gall-bladder is to the left separating the quadrate from the left lobe, the fossa of the inferior vena cava separates the Spigelian from the left lobe, the umbilical fissure lies between the right and quadrate lobes, the fissure of the ductus venosis lies between the Spigelian and right lobes. The gall-bladder lies on inferior surface of the liver, the body running backward upward and to the right. The portal vein and the hepatic artery pass to the liver in front of the foramen of Winslow, accompanied by the hepatic duct; the artery to the right, the duct to the left, the vein behind both.

Stomach. The cardia is at the right, the pylorus at the left, the greater curvature's convexity is to the right. The position of the intestines is reversed, the cecum being on the left, the ascending colon and sigmoid flexure on the right side. The mesentery is attached from right to left. The spleen is on the right. The left kidney is lower than the right. The left renal artery passes behind the inferior vena cava. The right ovarian vein empties into the right renal vein. The pancreas is transposed in position likewise, the head being to the left, the tail in the right. The aorta lies to the right of the vertebral column, the inferior vena cava to the left.

Since 1895 most of the cases have been recognized

FIG. 4.—Abdominal viscera: TC, transverse colon; Sp., spleen; A, abdominal aorta; Vc., inferior vena cava; S, sigmoid; R, rectum; B, bladder; CC, caput coli; IC, ileocecal valve.

ante mortem. The greater prevalence of the condition in men is probably due to the greater number of males admitted into hospitals, the larger number of cases in persons from 10 to 30 years is probably explained along similar lines.

We wish to thank Dr. R. C. Hamill for his kind assistance in making the photographs.

MEDICAL RECORD.

New York, January 22, 1910.

THE DELINQUENT CHILD IN ENGLAND.

THOSE in authority in Great Britain have become impressed, not only with the necessity of checking infantile mortality, but also with the vast importance of bringing up the young in a healthy manner, so that they may be mentally and physically fitted to be of service to and not a burden upon the State. Considerably more than two-thirds of the population of England reside in cities and towns, and a large proportion of the population is reared under disadvantageous conditions from physical, mental, and moral health aspects. Child life in the slums of large cities has little chance of developing properly, and unless steps are taken to better conditions, the human output of many urban districts will prove a canker rather than a fruitful blossom on the body social and politic. It is recognized everywhere now, and America was among the first countries to appreciate the fact and to act upon it, that children must be cared for if a nation is to prosper. Children brought up in bad surroundings cannot be expected to be of benefit to the community, and if their parents are unable or unwilling to show them the right way by example and precept, in self defence others must take this charge upon themselves. Neither nations, states, nor municipalities can afford to witness the wasting of the human raw material without putting out a hand to prevent this eventuality.

Dr. Walter Lindley was commissioned in the early part of last year by the Government of California to visit England in order to observe the manner in which delinquent children are treated in that country. His report has been published recently in pamphlet form. On the whole, Dr. Lindley was favorably struck with what he saw in England, and is of the opinion that rapid advance in the right direction is being made in the training of the English rising generation of the poorer class. The Children's Act of 1908 has already had an excellent effect. Before this act came into force mothers of the laboring class were in the habit of taking their young children and children in arms into saloons, where they drank themselves and frequently gave their children drink. The Children's Act prevents this abominable custom, and protects young children as far as is possible by law in several other ways from contracting vicious habits by dint of example and environment. The public school system of England is progressive, that is to say, after the school course proper is over, facilities are provided for learning a trade, or in the case of defective children assistance is given their parents to put such in the way of earning a livelihood. It is recognized, too, that insufficient nourishment and ill health are potent causes of so-called delinquency in childhood. Therefore, in some districts children are given free meals, and outdoor schools have been established with the object of counteracting these causes to some extent.

For the care of children who have been actually declared to be delinquent, three classes of schools have been founded. The Day Industrial School, The Industrial School, and the Reformatory. The first two schools are for delinquent children under fourteen, while to the reformatory school are committed those between fourteen and sixteen. At the day industrial school the child spends the entire day from between 6 and 7 A. M. to 6 P. M., is given baths, three good meals, and in addition to the ordinary school branches of training, if a boy, is taught a trade; and if a girl, sewing and cooking. The residential industrial school is very similar to the State industrial schools of this country, except that no children are admitted over fourteen. Juvenile reformatories are similar to the industrial in their equipment and routine of work, the chief difference being the age admittance. As has been pointed out previously in the MEDICAL RECORD, the industrial school and reformatory system is based on that of this country, and those responsible for the innovation in England have no hesitation in acknowledging their debt in this connection to the United States. However, in one respect, they differ wholly, none of the English reformatories is government or municipal. They have all been established and controlled by philanthropic voluntary organizations. Toward their upkeep, the national government and the municipalities contribute a sum averaging $2 a child per week.

The flocking of the British people to large centers of population and the consequent overcrowding of these places have brought about poverty, have bred and fostered vice and disease, and have rendered necessary the establishment of means and institutions whereby and in which the young may be given the opportunity of living under healthy conditions and of being taught to become useful citizens. Whether large institutions supply the most efficacious opportunities for achieving this object is a debatable point. Dr. Lindley in his pamphlet notes that France follows a totally different system with the same end in view. The Government of France sends her delinquent children to an agricultural family, pays a stated sum per week, and pays for the child's clothing and doctor's bill. The child must be sent to a public school. The cost of this procedure is stated to be far less than of maintaining a child in an institution, and it is further asserted that such children usually remain on the soil and become independent citizens. The Barnado Homes in England follow the placing-out system in

the country with a large proportion of their waifs and strays with much success. The problem of how to care for the urban child population is insistent in all civilized countries. In England it is present in its most accentuated form. It is satisfactory to record that the question there is being grappled with intelligently and vigorously, and that in the words of Lindley, "the strong, independent, self-assertion of England is being turned towards the redemption and uplifting of her own."

TUBERCLE BACILLI IN THE BLOOD.

A YEAR has now elapsed since Rosenberger read his paper before the Pathological Society of Philadelphia describing a simple method by which he was able to demonstrate tubercle bacilli in the blood in practically all cases of tuberculosis, including not only the advanced cases, but also those in the most incipient stages of the disease. Few contributions in recent years have aroused such interest among the students of tuberculosis as this article of Rosenberger's, as it not only made necessary a revision of some of the well-established ideas on the subject of the disease, but also gave promise of furnishing the profession with a simple, harmless, and sure method of diagnosing the condition in the stage in which there is the greatest chance of recovery. The result was that immediately, in nearly every American, and many of the European institutions for the study or treatment of the disease, investigators set to work in an effort to confirm the findings. The results were from the first discouraging, as, with but one or two exceptions, all of the workers reported either absolutely negative results or results positive in such a very small percentage of the cases as completely to destroy the value of the test for diagnostic purposes.

The latest report upon the subject appears in the January number of the *American Journal of the Medical Sciences*, in which Burville-Holmes of the Phipps Institute in Philadelphia reviews the literature and reports his own studies. In his paper the author not only shows by the work of himself and many others that the percentages of outspoken cases of tuberculosis in which acid-fast organisms could be found in the blood was extremely small, but also that it was no larger than in a considerable number of control cases in which there was no suspicion of the disease. At the same time Rosenberger has continued his studies and has increased his statistics from fifty-six to three hundred cases, in which he has found acid-fast bacilli in every instance. Such discrepancies between the findings of the different observers were at first hard to explain, and remained a decided mystery until Burnham and Lyon, and more recently Brem, showed that in their own cases at least the distilled water used for solutions and stains showed, when the smears were made by the addition of a trace of albumin, the presence of acid-fast bacteria in every case. This finding is also confirmed by Burville-Holmes in that all but one of his positive findings were reported from the Bryn Mawr Hospital, where the water was found to be contaminated, while the cases from the Phipps Institute, in which the water was pure, the blood findings were as uniformly negative. The general consensus of opinion among students of tuberculosis appears to be that Rosenberger's results, which at first appeared to be so brilliant and promised to be of such great value in the diagnosis of phthisis, were in fact the result of a very simple error in technique, and that, though it is possible to demonstrate the tubercle bacillus in the blood in rare instances, these are so extremely infrequent as to give the test practically no value from the point of view of the clinician.

This whole subject of the differentiation of the acid-fast bacilli is one that calls for more thorough investigation by bacteriologists. There are so many organisms, some, like the grass or hay bacilli, almost universally present, which are with difficulty decolorized by acids, that this characteristic in itself is of little importance. In addition to the grass bacillus we find the smegma bacillus, Lustgarten's bacillus, the bacillus of leprosy, the tubercle bacillus, and other microorganisms which have this peculiarity in common, and he would be rash indeed who would pronounce any given bacillus that of tuberculosis or of leprosy, in the absence of corroborative clinical symptoms or culture tests, merely because it was acid-fast. Unfortunately for diagnostic precision, the acid-fast characteristic can be regarded as suggestive only and not by itself as conclusive.

THE TREATMENT OF CONGENITAL DISLOCATION OF THE HIP DURING INFANCY.

THE date of election for the reduction of a congenital dislocation of the hip joint has been a subject of some discussion among orthopedic surgeons, the main arguments being concerning the upper age limit at which the operation may be performed with a reasonable hope of success. Lorenz first gave five years as the upper limit for bilateral dislocations and six years for unilateral ones. With improved technique, however, this has been raised, and children even as old as twelve years have been treated successfully. As to the youngest age at which the reduction should be done, there has been more unity of opinion. Practically all have agreed that it should be as early in life as possible; that is, as soon as the child has learned to control his excretory functions and has ceased soiling his clothes and the bed. This limit has been accepted on account of the extreme difficulty in keeping the plaster bandage clean, and preventing soiling and consequent inflammation of the skin at an earlier age. In the *Berliner klinische Wochenschrift* for December 13, 1909, however, Joachimsthal of Berlin reports some cases in which the lower age limit has been lowered with excellent results. The patients were infants varying from four to six months of age. The dislocations were reduced by manipulation and the thighs put in the usual position of abduction and marked flexion. Instead of the ordinary circular plaster dressing, the procedure was carried out by placing the child on its face and moulding to the back of the body and thighs a plaster bed, cut wide in the region of the anus. This was protracted by covering it with rubber tissue, and when it had hardened, the child was bandaged to it by means of gauze. By this simple procedure the dressings were kept fresh and clean, the bandages being changed

every two days, while the child lay on its abdomen. The results were striking. The skin remained healthy, and at this tender age the head of the bone showed a much greater inclination to remain in the acetabulum than is usual with older children. The plaster splints were removed in three to four weeks, and the results, as shown by the *x*-ray, as well as by the functional activity of the limbs, appeared to be perfect.

Septicemia Following Submucous Resection of the Nasal Septum.

The December issue of the *Laryngoscope* contains an interesting account by Harold Hays of two cases of septicemia following this now common operation on the nasal septum. One patient recovered and the other died. Such a severe complication seems rather rare according to the literature of the subject and conference with the author's colleagues here in New York. He has found several references to septicemia following septal abscess the result of trauma, but no one has admitted to him the existence of any serious complication following submucous resection. Of the author's two patients, the first died and the second recovered. Both were young Irish girls of about the same age and build, and both had had marked nasal symptoms for two years. Both were unusually bright and well educated, and both were stenographers. In Case 1 symptoms came on two days after operation, and death on the eighth day after. Careful examination was made for a focus of suppuration, but none was found. The symptoms were typical of septicemia. In Case 2 the symptoms came on two days after operation; on the sixth day the patient was placed under chloroform anesthesia and a very careful examination was made. This resulted in the location of a pus pocket well up above the middle turbinate. About half a dram of thick, ropy pus was evacuated. An immediate recovery took place. The author says that an examination under general anesthesia might possibly have located a suppurating focus in Case 1. He finds in the venous anastomosis of the upper nasal site a reason for the recurrence of cavernous sinus thrombosis following septal abscess. The note of caution he utters is a most timely one.

News of the Week.

Suggested Reforms in the American Medical Association.—The following resolutions were adopted by the Chicago Medical Society at a meeting held January 11, 1910: *Whereas,* the Chicago Medical Society is an integral part of a constituent society of the American Medical Association, and therefore vitally interested in the welfare of that great organization, and *Whereas,* certain conditions exist which menace the best interests of the members of the American Medical Association, and of the profession at large; *Therefore, be it Resolved,* That the Chicago Medical Society, in council assembled, recommends the following changes in the policies and management of the American Medical Association:

1. The laws should be so amended that no one person will be permitted to hold, at the same time, more than one executive or honorary office in the Association.

2. The office of General Secretary and the positions of Editor and Manager should be separated, and no person should be permitted to fill more than one of these places at one time.

3. The offices of Editor and Secretary should be filled only by men educated in regular scientific medicine and of unimpeachable professional records.

4. The number of Trustees should be increased.

5. All officers and employes whose duties involve financial responsibility should be bonded.

6. The laws governing admission to membership in the American Medical Association should be so amended as to make it mandatory upon the Secretary to enroll applicants who have complied with the provisions of the by-laws governing the same.

7. Space should be set apart in the *Journal* for free and courteous discussion of the policies and methods of the Association, or for any other matters which may appeal to the membership at large as bearing upon the interests of the Association.

8. Provision should be made for the initiative and referendum.

9. No member should be expelled from the Association without a fair trial and full hearing.

10. No person who is a general officer or member of the House of Delegates or Board of Trustees or an employe of the American Medical Association shall be eligible to serve as a general officer or member of the House of Delegates or Council of any constituent Association.

Be it Further Resolved, That the Secretary of the Chicago Medical Society be instructed to publish these resolutions in full in the Bulletin of the Society, and to transmit a copy of the same to the *Journal of the American Medical Association* and to the editors of the various State journals.

The Medical School of Columbia University.—The Trustees of Columbia have made public a plan for the removal of the College of Physicians and Surgeons from its present location on West Fifty-ninth street to a commanding site on Morningside Heights, where the other faculties of the University are now situated. A large part of the necessary land has been obtained through the generosity of William K. Vanderbilt, George J. Gould, Frank A. Munsey, and a fourth anonymous contributor, and it is expected that the remaining portion will also be acquired through gift. On this site, which occupies an entire block, it is intended to establish a medical school, the equipment of which, in the way of lecture rooms, laboratories, a museum, and other buildings, will be the equal of any in the world. The establishment of the College on Morningside will also bring it into more intimate relations with the University, for, as the Trustees state in their announcement of their plan: "Medical students, not only at Columbia but generally elsewhere, are outside of the associations and attractions of academic residence and of academic opportunity. The proposed rebuilding will bring both teachers and students of medicine into intimate relationships with teachers and students in other parts of the university."

Hospital Bureau of Standards and Supplies.—Representatives of the larger hospitals of New York City met at the Roosevelt Hospital recently and organized the Hospital Bureau of Standards and Supplies. The bureau will establish immediately a purchasing agency and put in charge of it a trained buyer. It is estimated by Mr. Thorne, treasurer of the Presbyterian Hospital, who organized the purchasing departments of the Union and Southern Pacific railroads, that a saving of from 10 to 20 per cent. will be effected in the purchase of hospital supplies.

Typhoid Fever in Montreal.—There is what appears to be a somewhat serious epidemic of typhoid fever in Montreal at the present time. According to some accounts, there are 3,000 cases, while some of the lay papers assert that there are as many as 6,000 cases of the disease in the largest city of Canada. It is certain, whatever the exact number of the sufferers from the malady may be, that the hospitals can hold no more, and that a special hospital has been prepared for their accommodation. For many years typhoid fever at certain seasons has been more or less prevalent in Montreal, and its prevalence is attributed to the pollution of the water supply. Montreal derives its water supply from two sources, the city supply and the Montreal Water and Power Company. The city provides about four-fifths of the total supply and the Water and Power Company one-fifth. Both obtain water by pumping from the St. Lawrence River, and in both cases water is delivered direct without any provision whatever for purification. The St. Lawrence and Ottawa rivers receive a large part of the sewage of Ontario, some of the sewage of Quebec, and some of the sewage of New York State, and this is the water that Montreal inhabitants must drink. At the commencement of winter when ice begins to cover the river, typhoid fever generally manifests itself in Montreal. The prevalence of the disease is more widespread this winter than usual, and it appears likely that steps will soon be taken to safeguard the water supply. As in Toronto the sewage will be disposed so as not to menace public health, and a system of water filtration will be introduced.

High Rate of Infantile Mortality in Toronto.—The Section of State Medicine of the Academy of Medicine, Toronto, has presented the following resolution: That this section should direct the attention of the Committee of the Academy of Medicine to the high rate of infantile mortality in the city of Toronto and in the Province of Ontario for 1907 as shown by the thirty-eighth annual report of the Registrar-General just issued, and would respectfully request the Academy to appoint a special committee to consider and report on the same. During 1907 the deaths under one year of age in Toronto were 1,313. Births 6,600. Death rate per 1,000 births, 196. Deaths under one year of age in Ontario, 8,041. Births, 53,584. Death rate per 1,000 births, 150.

Scarlet Fever in Toronto.—Scarlet fever is somewhat rife in Toronto. The isolation fever hospital is full to its capacity of seventy-five, and there are several cases which are awaiting admission.

Milk Famine in Chicago.—Owing to the stalling of trains in the neighborhood of Chicago, caused by the snow storm of January 14, the city suffered from a milk famine. Hospitals reported that patients depending upon milk for subsistence had been deprived of it. Children's homes and asylums in several instances were without their daily supply, and physicians reported the milk famine to have had bad effect in patients needing the nourishment.

Hook Worm in Samoa.—A dispatch from Samoa states that it has been discovered that from 40 to 50 per cent. of the natives of the Samoan Islands suffer from uncinariasis.

"Kissing the Book" Abolished in London.—The time-honored but unsanitary custom of kissing the Bible when being sworn has been abolished in the Lambeth Police Court in London.

Endowment for the Study of Puerperal Sepsis.—The Society of the Lying-in Hospital of New York has received from Mrs. Helen Hartley Jenkins $25,000 to enable the hospital to make a special study of puerperal fever. The fund is to be known as the Emma Hartley Endowment, in memory of her mother.

Charitable Bequest.—By the will of the late Anna Eliza Porter of Philadelphia the sum of $10,000 is bequeathed to the Methodist Episcopal Hospital for a free room to be known as the Porter Memorial, with $200 additional for the equipment of the room, provided that the Trustees of the Hospital keep hanging in the room pictures of the testatrix's father and mother.

D. H. Beeckman Delatour has resigned as Surgeon-in-Chief to the Methodist Episcopal Hospital, Brooklyn. Dr. Delatour was the first interne of the hospital, and during the past twenty-two years has served as assistant attending surgeon, attending surgeon, and surgeon-in-chief.

Dr. George W. Vandegrift of New York City has been apopinted visiting oculist to the Jewish Protectory and Aid Society, Hawthorne, N. Y.

The International American Congress of Medicine and Hygiene will be held May 25 in Buenos Ayres, Argentine Republic, in commemoration of the first centenary of the May revolution of 1810. In order to facilitate the contribution of papers and exhibits from the United States, there has been appointed by the President of the Congress, Dr. Eliseo Cantôn, and the Minister of the Argentine Republic at Washington, a committee of propaganda, of which Dr. Charles H. Frazier of Philadelphia is chairman, and Dr. Alfred Reginald Allen of Philadelphia is secretary. The Congress has been divided into nine sections, each section being represented in the United States by its chairman in this Committee of Propaganda, as follows: I. Biological and Fundamental Matters, Dr. W. H. Howell, Baltimore, Md. II. Medicine and Its Clinics, Dr. George Dock, New Orleans, La. III. Surgery and Its Clinics, Dr. John M. T. Finney, Baltimore, Md. IV. Public Hygiene, Dr. Alexander C. Abbott, Philadelphia, Pa. V. Pharmacy and Chemistry, Dr. David L. Edsall, Philadelphia, Pa. VI. Sanitary Technology, Dr. W. P. Mason, Troy, N. Y. VII. Veterinary Police, Dr. Samuel H. Gilliland, Marietta, Pa. VIII. Dental Pathology, Dr. George V. I. Brown, Milwaukee, Wis. IX. Exhibition of Hygiene, Dr. Alexander C. Abbott, Philadelphia, Pa. It will not be necessary for one contributing a paper or exhibit to the Congress to be present in person. Arrangements will be made to have contributions suitably presented in the absence of the author. The official languages of the Congress will be Spanish and English. Members of the following professions are eligible to present papers or exhibits: Medicine, pharmacy, chemistry, dentistry, veterinary medicine, engineering, and architecture. Papers may be sent direct to the chairman of the particular section for which they are intended, or to Dr. Alfred Reginald Allen, secretary, 111 South Twenty-first street, Philadelphia, Pa.

Far Eastern Association of Tropical Medicine will hold its first biennial meeting at Manila, P. I., March 5 to March 14, 1910. The association was established with the idea of bringing together workers in tropical medicine in that portion of the world for an exchange of ideas and to foster the spirit of scientific investigation which has already brought

forth such excellent results in certain of the eastern countries. The program is as follows: At Manila—Saturday afternoon, March 5, opening session; Monday, March 7, Protozoölogy, Helminthology; Tuesday, March 8, Cholera, Plague, and Leprosy; Wednesday, March 9, Surgery and Obstetrics, Diseases of Children; Thursday, March 10, Fevers in the tropics, including Malaria, Typhoid, etc.; Friday, March 11, Dysenteries, Beriberi; Saturday, March 12, Tuberculosis; Saturday night, en route to Baguio. At Baguio—Monday, March 14, Climate, Hygiene, and Sanitation; Business session.

The New York Academy of Medicine.—The Section on Medicine has issued the following statement: It is now generally agreed that in medical meetings the most instruction and profit is afforded by the practical presentation of patients, of specimens with case records and of apparatus. It is, therefore, considered advisable to increase if possible the clinical features of the program of the meetings of the Section on Medicine and to present papers, only when some work of especial importance is to be reported. In order to obtain a fair presentation of the great wealth of clinical material which the institutions of this city contain, a list of the hospitals, dispensaries, laboratories, and medical schools has been prepared and to each a meeting has been assigned.

A Portrait of Dr. Flexner.—The Permanent Portrait Committee of the Medical Department of the University of Pennsylvania has, during the past few years, almost completed the collection of portraits of former professors in the Medical School. These portraits now hang in the halls and lecture rooms of the new medical laboratories and thus connect historically the new home of the Medical Department with memories and traditions of teachers of the past century and a half. Of the six professors not at present represented in this collection, one is Dr. Simon Flexner, who was Professor of Pathology for the years 1899 to 1903. A special committee has been appointed to procure Dr. Flexner's portrait. This committee, therefore, addresses the former students, associates, and assistants of Dr. Flexner in the hope that they may contribute to the Portrait Fund and thus aid in completing the historical portraiture of professorial succession, so wisely planned by the Permanent Committee. Checks should be made payable to the treasurer, Dr. William Pepper, 1811 Spruce street, Philadelphia, Pa.

The Late Dr. Moskievitz.—At a recent meeting of the Medical Board of the Har Moriah Hospital the following resolution was adopted: *Whereas,* Dr. Max Moskievitz died on the 3d day of January, 1910, in the ripeness of his years, and *Whereas,* Dr. Moskievitz by the kindness of his nature, his integrity and the idealism of his character, the high attainments of his intellect and the conscientiousness and ability with which he served the interests of the Har Moriah Hospital, has endeared himself to the members of the Medical Board; be it *Resolved,* That the Medical Board of the Har Moriah Hospital deplore his untimely death and the loss of his beneficent activities in connection with the hospital, and be it further *Resolved,* That the Medical Board, with expressions of their deepest sympathy transmit to his family a copy of these resolutions and publish them in the medical press of this city. A. V. Moschcowitz, M. D., Leopold Stieglitz, M. D., Committee.

Obituary Notes.—Dr. Alfred H. Hoadley of Northampton, Mass., died December 29, 1909, aged 54 years. Dr. Hoadley was a graduate of the Albany Medical College in 1886, and was a member of the Hampshire County Medical Society, the Massachusetts Medical Society, and the American Medical Association. He was attending surgeon of the Dickenson Hospital.

Dr. William Jackson McHench of Brighton, Mich., died in Bratentown, Fla., January 1, 1910, aged 70 years. He was a graduate of the University of Michigan in 1859.

Dr. Uzziel Ogden of Toronto, Canada, died January 4, 1910, aged 82 years. He was a graduate of the Victoria University in 1849. In 1855 he assumed the chair of midwifery and diseases of women and children in the Toronto School of Medicine. Later he was professor of gynecology in the Medical Faculty of Toronto University. He founded the *Canadian Journal of Medical Science.*

Dr. William Bradley Chase of Lynn, Mass., died at his home January 4, 1910, aged 76 years. He was a graduate of the Jefferson Medical College in 1857.

Dr. G. S. Cleland of Toronto, Canada, died at his home January 3, 1910. He was a graduate of the Toronto School of Medicine in 1882.

Dr. Ellery Denison of New York City died at his home January 14, 1910, aged 83 years. He was a graduate of the New York University Medical College in 1853, and was a member of the New York County Medical Society, the Medical Society of the State of New York and the American Medical Association. For many years Dr. Denison was attending physician to the Northern Dispensary and the Home for Aged and Cripples.

Dr. John H. Ewing of Flemington, N. J., died at his home January 14, 1910. He was a graduate of the Jefferson Medical College in 1877, and was a member of the Hunterdon County Medical Society and the Medical Society of New Jersey.

Dr. Henry Daniel Shonts of Chicago died January 2, 1910. He had practised for many years in Erie, Pa., but had been retired since 1894, and removed to Chicago. Dr. Shonts was 87 years of age.

Dr. L. J. Worley of Washington Court House, Ohio, died January 6, 1910, aged 59 years. He was a graduate of the Eclectic Medical Institute of Cincinnati in 1887.

Dr. Andrew M. Moore, U.S.N., retired, died in Naples, January 13, 1910. He was born in Tennessee on December 25, 1845. He was graduated from the medical department of the University of Pennsylvania in 1869 and was later appointed an Assistant Surgeon in the navy, his first assignment being at the Philadelphia Naval Hospital. He was later transferred to the coast survey steamer *Bibb,* and later assigned to the *Saco* on the European and Asiatic stations. In 1874 he was promoted to Passed Assistant Surgeon, and was called to the New York Naval Hospital, where he served for a year, later serving on the Presidential yacht *Mayflower.* After serving on three of the largest battleships in the navy he was promoted to Surgeon in 1881. While serving as Surgeon of the Mare Island station, in California, Surgeon Moore was retired in 1893.

Dr. P. Brough Montgomery of Chambersburg, Pa., died at Buena Vista, Fla., on January 8, at the age of 48 years. He was graduated from Bellevue Hospital Medical College in the Class of 1886.

Correspondence.

REDUCED TYPHOID MORTALITY.

To the Editor of the Medical Record:

Sir:—The excellent résumé of vital statistics published in the January 8 issue of the Medical Record moves me to call attention to the remarkable reduction of mortality per cent. in typhoid fever which I discovered in the statistics of this disease, furnished me by courtesy of Dr. Cronin of the Health Department, for the purpose of studying the probable influence on its mortality of a better management. The following figures may interest your readers and furnish food for reflection:

Typhoid Fever—Old City of N. Y., Manhattan and Bronx.				Present City, Greater N. Y.			
Year.	Cases.	Deaths.	Mort. % Omitting Fractions.	Year.	Cases.	Deaths.	Mort. % Omitting Fractions.
1890	1100	352	32	1898	2226	676	30
1891	1342	384	21	1899	1950	546	28
1892	1140	400	30	1900	2658	718	27
1893	1008	381	37	1901	2748	727	26
1894	792	326	40	1902	3871	764	18
1895	965	322	33	1903	3671	653	17
1896	1002	297	29	1904	3412	661	16
1897	1004	299	29	1905	4326	649	15
				1906	3467	639	18
				1907	4426	740	16
				1908	3058	536	17

These figures indicate clearly that while there is still much room for betterment there has been a sudden and decided fall in the mortality of typhoid fever in New York City since 1901. It is my purpose to investigate the reasons for this favorable change, to ascertain why the latter has continued so uniform, varying only two degrees in six months before and after 1902, during the high as well as during the lower rate of mortality, and especially to discover if the type of the disease has been changed by more correct management of the case. In the meantime the question arises: What influence on the conduct of cases of typhoid fever by the average doctor has followed the agitation of this subject in our medical societies during the nineties and especially the convincing clinical investigations of W. Gilman Thompson and the late H. P. Loomis published respectively in 1902 and 1903? In his text book on Practice, Thompson stated that the mortality from typhoid fever in the New York and Presbyterian Hospitals had fallen from 16 to 6 per cent. by reason of the systematic use of the Brand bath. Dr. H. P. Loomis stated in a painstaking inquiry about the Brand bath in the New York hospitals, the details of which were presented to the Practitioners' Society and published in the Medical Record of January 10, 1902, that this bath had reduced the mortality 50 per cent. since it began to be used systematically in the hospitals referred to. The Brand bath (fifteen minutes at 70° F. every four hours, with constant friction, when the rectal temperature is above 102.6° F., when the patient is not normally sleeping) is, as I have long maintained, rarely applicable in its strictest sense in civil hospitals, because the patient is rarely admitted during the first days of the disease. The reason of the marvelous results of Brand and Vogl in over 2,000 cases (mortality of less than 3 per cent. by Vogl and 1 per cent. by Brand) may be readily found in the fact that in the military hospitals soldiers are relieved from duty immediately upon evidence of fever and being sent to the hospital are at once bathed on suspicion. That this may readily be done in private practice is indisputable. Since I have adopted this practice ("Theory and Practice of Hydrotherapy," William Wood & Co., 1908, page 331) the cold friction bath has not only facilitated diagnosis but influenced the prognosis in a very satisfactory manner. When the rectal temperature is 103° F., or over, a bath of 90° F. is given in the bathroom for twelve minutes with friction. If the temperature is still 103° or more in four hours a second friction bath of 85° F. is administered. This is repeated every four hours under the same conditions, reducing the temperature of the water five degrees for each successive bath until 70° F. are reached. If one of these baths reduces the rectal temperature two degrees or more, typhoid fever may be excluded. The smaller the temperature reduction in the *rectum* the more probable is the diagnosis of typhoid fever during the first week of the illness. These mild baths are rarely objected to and may thus inure the patient and the sentiments of the family to the cold friction bath, when the diagnosis of typhoid fever demands it.

While the strict Brand bath is the ideal method of managing typhoid fever, I realize that conditions do not always favor its adoption. It is heroic, it appears to be and is severe, and it makes enormous demands upon all concerned. If the physician has the courage of conviction, he will never fail in obtaining consent. If for any reason this is impracticable, I would reiterate what I said before the Philadelphia County Medical Society several years ago. The following scheme of "Dont's" affords a summary of what to do and what to avoid in the application of cold water in febrile diseases:

Don't bathe with cold water to reduce temperature, but to refresh the fever-stricken patient.

Don't permit cyanosis or chattering of the teeth; stop.

Don't stop bathing because the patient complains of chilliness, unless the teeth chatter. Don't raise the bath temperature on the latter account; shorten the bath and increase friction.

Don't neglect friction during every cold procedure; it prevents chilling.

Don't use the Brand bath in a bathroom. Use a tin tub alongside the bed.

Don't give up cold bathing because the ideal Brand bath is not obtainable; other procedures are useful.

Don't use the ice coil to the abdomen; it has no refreshing effect and renders the skin beneath it cyanotic.

Don't lose sight of the fact that the chief aim of all cold procedures is reaction.

In brief there is rarely a case of typhoid fever to which some form of cold water procedure may not be adapted with the result of refreshing the central nervous system and endowing the entire organism with a capacity of resistance against the lethal factors which lie primarily in depreciation of the nervous system and of the circulatory apparatus.

135 W. Seventy-third Street.

OUR LONDON LETTER.

(From Our Regular Correspondent.)

ROYAL SOCIETY OF MEDICINE, ANNUAL DINNER, REPORT ON PREMISES—LACTIC ACID BACILLI—LYMPHATISM AND DEATH DURING ANESTHESIA—LIVINGSTONE COLLEGE—PATHOLOGIST FOR LOCAL GOVERNMENT BOARD—HEALTH OF LONDON—OATHS' ACT, 1909.

London, December 31, 1909.

The Royal Society of Medicine, in consequence of its success since its formation by the amalgamation of several societies, has begun to find the accommodation of its house rather restricted, and for some little while there have been suggestions that larger premises should be obtained. The question has been considered with great care by a committee, which has recommended a building scheme at a cost of about £50,000. This has been considered at a special meeting and, although supported by the council, was not adopted. There was, however, a manifest opinion that further accommodation was really required and the thanks of the meeting were accorded to the committee for so carefully investigating the matter and especially to Dr. A. Latham, who had been most active in considering it.

The annual dinner of the society was held on the 15th, at which nearly 200 were present. The president of the Royal Society, Sir A. Geikie, was one of the guests and proposed the toast of the evening, congratulating the Fellows on the success of the amalgamation and suggesting that some such scheme might be a good one for the Royal itself. Sir William Church, in replying, said the scientific work of the year had been satisfactory, instancing especially the discussion on heredity. The society, he said, now numbered 2,328 Fellows and 991 members. The library had been visited by 8,564 readers during the year and nearly 8,000 books had been borrowed. The expenses of publication were very great and perhaps the reports might be abbreviated without detriment.

Mr. Butlin and Dr. Moore also spoke, the former expressing a hope that the society might have a home worthy of its position to receive the distinguished persons who would visit them at the International Congress of Medicine.

In the Therapeutical Section there has been a capital debate on the value of the lactic acid bacillus as a remedy. It was begun by Dr. George Herschell, who insisted on the necessity of selecting only suitable cases—a precaution, one might say, equally necessary in every therapeutic investigation—and further on using only active preparations. He had to confess that he had only met with two or three solid prepara-

tions of all those being sold which contained any Bulgarian bacilli. His indications for the remedy were excessive putrefaction of proteins in the alimentary canal and autointoxication from the colon. He had met with success in such cases, but where the symptoms pointed to fermentation of carbohydrates the treatment was useless.

Dr. Goodbody said he had for the most part met with negative results in seeking for chemical evidence. Certainly the aromatic sulphates underwent no appreciable diminution.

Dr. V. Harley had had similar experience. There were no changes in the feces to correspond with the improvement reported in the symptoms. Such improvement was only met with in functional dyspepsias and there was no amendment when organic disease was present. Perhaps the good effects recorded were, after all, psychological.

Dr. Bullock had examined above twenty specimens of tablets sold without meeting any active bacilli, so he considered they should all be rejected as worthless.

Dr. J. W. H. Eyre had had some success in certain infections of the colon with pathogenic bacteria, but he had worked with his own strain of bacilli. Successive cultivations from the feces brought about rapid decrease of the pathogenic microorganisms.

Dr. Robert Hutchison was profoundly skeptical of the results claimed and was strengthened in his doubts by this discussion, which he hoped would check what seemed a mere craze. He would rather trust small doses of calomel to check intestinal putrefaction.

Dr. C. H. Miller had tried the treatment in rheumatoid arthritis. The general health of the patients improved, but not the arthritis.

Dr. Hertz doubted the existence of autointoxication. In a case of streptococcal infection of the bowel he had obtained rapid recovery from soured milk. The streptococci disappeared from the feces when the milk was given and he thought the remedy should be used.

Dr. Langdon Brown had seen indicanuria disappear under this treatment.

What is status lymphaticus? This question has often been put to doctors since the condition was put forward at a coroner's inquest as the cause of a death under an anesthetic. In the section devoted to these agents it is an appropriate subject of investigation, and to that section Drs. Bellamy Gardner and Salisbury Trevor have contributed a careful paper illustrated by photographs of frozen sections to demonstrate the position of the thymus and its relations to the esophagus, trachea, innominate, and aorta at the levels of the sixth cervical, first, third, fourth, and fifth dorsal vertebra, respectively. Further, they related six cases of sudden death in which there was enlarged thymus and general lymphatism. Two of these were aged nine and thirteen months. There were two boys of thirteen and fourteen years, a man of twenty-nine and a woman of thirty.

The woman had tropacocaine, one boy ethyl chloride, the other CE mixture. The infants and the man were not anesthetic cases. Percussion might be of use in diagnosing enlargement of the thymus and other glands, but the *x*-rays would be more decisive as to the relation of status lymphaticus to death under anesthetics. Dr. Buxton remarked on the confusion that exists in the records of these fatalities. Some common dyscrasia might be responsible for the conditions called lymphatism, thymic asthma, or death, and so on. Where there was pressure on the thymus the symptoms would be clear enough to forbid general anesthesia. But lymphatic hyperplasia of different degrees might be present without producing symptoms. Myocardial disease always accompanied status lymphaticus and was perhaps a part of it. Exceptionally weak vapors therefore should only be used and oxygen should also be given in such cases, even if they seemed robust. It was safer to assume a danger that might not exist than to overlook one that might be present without producing definite symptoms.

Dr. Spilsbury said too much had been made of the thymus. He had known it to atrophy in the usual way in childhood and grow again in later life. In 75 per cent. of deaths during anesthesia he had found signs of status lymphaticus.

Dr. Hewitt said an asphyxial factor, so slight as to be overlooked, was often present before sudden death. The heart was not so important if the respiration was absolutely free and the anesthesia not too profound.

Dr. Leonard Williams thought that very often decreased activity of the thyroid gland was present, and the other minor glands enlarged to supply the resulting deficiency.

Livingstone College was founded to enable missionaries to obtain some knowledge of medicine before entering on their work in parts where there were no European doctors. In the annual report just out regret is expressed that the great missionary societies do not make more extensive use of it. Dr. Macalister said at the meeting: "The men who have been trained here have taken their own proper platform as missionaries with a little knowledge of medicine, but not as medical missionaries, and they have done in their lifetime a splendid work." Dr. Stein, the Central Asian explorer, testified that he owed his recovery, if not his life, to an old Livingstone student. There is a deficit of £265 on the year's working, which should soon be liquidated, considering the importance of the training given for the special work of the missionaries. So long as a sufficient number of really medical men are not available to staff all the mission stations, it would seem that the training at Livingstone should be undergone by those who go to places where medical advice is not available.

This morning it is announced that the Local Government Board has appointed Dr. Eastwood, who was one of the pathologists of the Tuberculosis Commission, to be an additional medical inspector of the board, in order that he may undertake pathological investigations. The immediate object is to apply to public health work the results of the Tuberculosis Commission and insure the purity of foods in respect to tubercle. Investigations as to other infectious diseases in relation to public health will be included. Pathological diagnosis as already utilized by sanatoria will be further investigated and it is expected that by interchange of information good work will be encouraged and extended, and that coordination and standardization of bacteriological diagnosis will be secured. I congratulate Dr. Eastwood in having assigned to him a sphere of research wide enough to engage all his energies.

The report of the health committee of the County of London for the year 1908 has appeared. The birth rate and death rate for that year are the lowest that have been recorded since the returns were inaugurated. The London death rate has been declining for forty years. For ten years the decline has been almost regular. The fall in the birth rate has been almost uninterrupted for thirty years. The number of deaths per 1,000 births was the lowest ever recorded. The infant mortality for the last decennium has been lower in London than other large English towns. The death rate from epidemic diseases is also the lowest recorded, except from influenza and scarlet fever, which were above the average.

Last year Parliament conferred powers on sanitary authorities (1) to refuse to register or to remove from their registers the names of dairymen carrying on business in unsuitable premises; (2) to appoint health visitors; (3) to require proper provision for cooking in tenement houses; (4) to enforce certain regulations as to cleanliness, etc., in places where food is prepared.

To-morrow "The Oaths' Act 1909" comes into force. It dispenses with the disagreeable custom of "kissing the book," against which protests have long been made, substituting what is often called the Scotch form, although erroneously, for the lifting of the hand is an extremely ancient mode of swearing. Several references to it are in the Bible, the earliest in Genesis (Ch. 14, v. 22).

Progress of Medical Science.

Boston Medical and Surgical Journal, January 6, 1910.

Obstructive Calculous Anuria.—The conclusions of F. S. Watson are as follows: (1) The urinary secretion of an unobstructed kidney which is normal or but moderately diseased appears in a few instances to be suppressed by the influence of the so-called reno-renal reflex inhibition originating in the irritation and obstruction of the opposite ureter by an impacted calculus. (2) The proportion of bilateral to unilateral cases of renal calculus appears to be about 30 per cent. The relative number of cases in which both ureters are simultaneously blocked in the bilateral ones appears to be much larger than is generally stated, perhaps as high as 20 per cent. (3) The number of cases in which the unobstructed kidney, or perhaps both kidneys, possess a useful amount of functionally capable substance is larger than is generally stated. (4) In the absence of unfavorable symptoms, and

if the period of anuria has been but a short one, the effort should be made to reestablish the urinary secretion by passing ureteral catheters into both ureters and retaining them in position for several hours. This step may be supplemented by the administration of saccharine or physiological saline solution. Combining the latter with venesection probably adds to its efficacy. (5) The employment of oil injections with ureteral catheter above the point of impaction of the calculus should be given a more extended trial in the cases in which it is not known that the calculus is too large to be passed spontaneously. (6) Bilateral simultaneous nephrotomy should be given a further trial in all cases in which calculi exist in both sides, whether the two ureters are simultaneously obstructed or not; also in all unilateral cases in which the first kidney operated on is found to be functionally useless or very extensively diseased.

Non-Obstructive Anuria.—J. Pederson makes the following division of cases: Reflex, toxic, hysteric, anuria due to interference with or changes in the blood supply and changes in the blood itself, and anuria due to injury of the kidney. The paper is mainly occupied with references to the literature of the subject under these headings. Drugs that have been reported as causing anuria are chloroform, ether, calomel, bichloride, cocaine, carbolic acid, oxalic acid, turpentine, lead, sulphuric acid, phosphorus and cantharides. Among the infectious disease causes are scarlet fever, measles, diphtheria, yellow fever, and cholera. In regard to treatment, the various procedures that have proven of service are enumerated. All medical and surgical measures should be tried before operating. The ureteral catheter will often relieve reflex anuria. Radical cure, of course, demands the removal of the cause, be it in kidney, ureter, or cervix. Bevan would limit surgical intervention to cases in which there is increased tension, and holds that a preexisting profound toxemia contraindicates operation. Watson believes that it is important to ascertain whether the anuric kidney possesses sufficient secreting tissue, and says that at times it becomes a question as to which kidney to operate on first. In cases of calculous anuria, both organs should be exposed at the same time. One authority advises the use of sparteine in doses of from one to two grains hypodermically. The dose should be repeated in six hours. If the kidneys are sound, copious drinks and saline infusions may do much good. The presence of anasarca is the main contraindication. As a final resort, nephrotomy or decapsulation may give great relief, but this does not always mean a recovery. Under the head of last resort treatment, measures to ward off uremia are to be included. One authority advises deep anesthesia for the hysterical variety and hypnotic suggestion for the tendency.

New York Medical Journal, January 8, 1910.

Experimental Studies on the Etiology of Acute Poliomyelitis.—An elaborate paper is presented by I. Strauss and F. M. Huntoon. Their conclusions follow: (1) Acute poliomyelitis can be produced in a *Macacus rhesus* by intraperitoneal inoculation of the cord of a fatal human case. (2) Unsuccessful attempts to transfer acute poliomyelitis from one monkey to another by intraperitoneal inoculation have been made twice by Landsteiner and Popper and twice by us, and warrant the assumption that successful subinoculation by this method is an uncertain procedure. (3) The cerebrospinal fluid of acute cases does not contain the virus in an infective state, and the reported bacterial findings in the cerebrospinal fluid are either contaminations, or secondary invaders. (4) When the disease is clinically recognizable, namely, after the onset of the paralysis, the virus is probably no longer present in the blood, or at least cannot be used to produce infection in the monkey by intraperitoneal and intradural inoculation. (5) Histologically, the lesion in poliomyelitis is very similar to that in rabes. Furthermore, there occurs in rabies a type of ascending paralysis which is clinically identical with the ascending paralysis (Landry type) of acute poliomyelitis. The method of inoculation of animals with an emulsion of the cord which is employed in producing experimental rabies is similar to that employed now in causing experimental poliomyelitis. These facts point to possible analogy between the infective agent in both conditions, and to the fact that the virus is probably not of bacterial, but may possibly be of protozoan nature. (6) Acute poliomyelitis must now be classed among the infectious diseases. The character of its clinical symptoms and the facts which have been ascertained from a study of its epidemiology have for some time led to its being regarded as infectious. But the repeatedly successful inoculations of a lower animal has now demonstrated this beyond doubt. The only objection which can be made to this conclusion is that the disease may be of toxic origin. However, the lesions which the central nervous system present both in man and monkey are of an inflammatory rather than of a purely degenerative nature, such as toxins (diphtheria and tetanus) produce. Moreover, were the disease due to a toxemia, it would be difficult to explain the occurrence of a long and variable period of incubation after intraperitoneal inoculation.

Ruptured Triceps Due to Direct Violence.—D. P. Penhallow records one case occurring in a stout man of 35 years who was knocked down by a large box. A marked sulcus was found on the right arm about two inches above the olecranon when the arm was extended. On attempted forcible extension a large mass appeared on the inner and posterior surface of the arm with increase in the width of the sulcus, over which, three hours later and under ether, a vertical incision was made. It was found that the belly of the middle head of the triceps was completely severed and some few of the fibers of the internal head were also destroyed. When the arm was flexed, there was a separation of two inches between the distal and proximal ends, but when the arm was extended the ends approximated easily. The wound was washed out with warm saline solution and the muscle sutured with three rows of continuous catgut sutures No. 2 chromic, one row being placed anteriorly, the second in the middle of the muscle to obliterate the dead space, and the last row approximating the posterior edges. The surfaces came together easily, and there were no projecting muscle fibers. The fascia was closed with continuous chromic catgut No. 2. The skin was closed with interrupted silkworm gut sutures. Dry sterile dressings were applied. A ham splint was applied to keep arm in full extension. Primary union followed, and the sutures were removed on the eighth day. The splint was removed at the end of the third week and passive motion instituted. There were apparently no adhesions between muscles and fascia. Slight muscular thickening existed at the site of injury. The ultimate result was apparently perfect. Operation is advised in all injuries of this kind. In all cases in which the injury is severe the diagnosis should be comparatively easy, as there is marked loss of power of the parts so affected, and, when the muscle is contracted, there is a deep sulcus which is formed by the separation of the destroyed fibers. As the proximal fibers contract, they form a tumor mass which is known as a pseudohernia. This usually can be noticed in the more severe cases at the time of the accident, but may be overlooked in the more obscure forms where only a few fibers are involved. In some few cases which have not been recognized early, the pseudohernia may develop slowly and become evident only after the lapse of a few weeks.

A Duodenal Tube.—In a preliminary communication, M. Gross refers to a stomach tube devised by him in 1893, consisting of a thin rubber tube one-quarter of an inch in diameter and easily collapsible, an olive-shaped end piece, a glass receptacle to collect contents, and an aspirating mouthpiece to which a bulb could be attached. He has now devised a duodenal tube based on the same principles, except that it is longer, measuring 150 cm., being graded in sections of 10 cm. each. Then a number of holes arranged behind the solid body of the olive-shaped end piece through which the fluid contents are expressed. Patients who had the ordinary stomach tube introduced before, possibly only once, swallow the softer tube with ease, and are even able to aspirate the contents themselves while the tube is in place. With a few movements of deglutition the olive-pointed end rapidly reaches the cardia, and passes it. This can easily be controlled by observing that the air blown into the tube no longer escapes at the top, and that the figures marking the sections indicate an insertion of 40 to 45 cm. Up to this stage the tube is never allowed to descend more than 50 cm., a depth at which the olive-shaped end of the tube will hang freely in the cavity of the stomach. The patient is then instructed to turn over on his right side, to desist from swallowing, and simply to allow the tube to glide down, which it will do to a depth of 65 or 70 cm. This being accomplished, the patient is directed to turn over on his back, and in this position the tube is slowly and carefully guided further down, always following the automatic pull of the tube, and without swallowing, until a depth of 80 to 85 cm. is reached. After from five to ten minutes the contents, which in nearly all cases will prove slightly inspissated and of a gold yellow color, are withdrawn. Sometimes there is a more fluid and fluorescent consistency. The substance is not always alkaline, but it always shows characteristic signs of its duo-

denal origin, both macroscopically and chemically. Sometimes the alkaline reaction changes almost instantaneously into acid, especially when there is hyperchlorhydria. Pyloric spasms indicated by inability to obtain any contents at all are overcome either by withdrawing the tube slightly or by a brief wait. In some instances a few deep inspirations will help the flow of the duodenal contents.

The Traumatic Neuroses—a Psychological Mosaic.—The diagnosis of traumatic neurasthenia is made, as Pearce Bailey understands it, when the mental symptoms are those of irritability and fatigue, and when no such neurological symptoms as paralysis, convulsions, anesthesia, and contraction of the visual field are present. He presents this form of neurosis as a disturbance in the mind produced by a single painful experience. Once created, it, like other painful experiences, would naturally tend to fade and lose in influence. But if conditions are such that it is kept ever present in the patient's consciousness, it may bring about painful and disabling mental states. The symptoms brought about by these mental states are similar to those of various functional nervous diseases. But they differ from them in having a definite point of departure; in being formulated and controlled by a characteristic environment, and in that recovery cannot be expected until that environment is broken up. Hypothetical cases are described, and the general environment in which a patient lives after a severe accident is accurately described. The traumatic neurosis is, says the author, a psychological mosaic. The initial accident is the quarry which supplies the stone. But the shaping of the separate pieces, the chiseling of their edges and the compactness with which all are used to form a complete design result from succeeding force. Variations of design can be traced to many causes. As regards the purely subjective symptoms, such, for example, as headache and liability to fatigue, these owe their origin, in part at least, to an abnormal egocentricity, a natural result of the legal systems. The so-called objective symptoms, the anesthesias, the paralyses, and the like, can usually be traced to some suggesting circumstances unavoidable in medicolegal examination. The difference in design observed in different countries reflect the differences in law and in method of procedure, regarding the compensation of injured persons. Our large verdicts call for more dramatic symptoms than the small weekly sums allowed to injured workmen in Germany.

Journal of the American Medical Association, January 8, 1910.

Melanoma.—J. A. Fordyce discusses the etiology and pathology of the type of sarcoma of the skin known as melanoma. He thinks that possibly the importance of congenital pigmented moles in the origin has been overestimated. The majority of people have these, but only a few of them become malignant. They may arise from the unpigmented skin. He reports two cases of melanoma of the foot, which, with the face, is one of the sites of predilection of these tumors, though they may occur elsewhere, even on internal organs. The rule is for the melanomata to form more metastases than any other tumors, dissemination taking place both by the lymph and blood streams, and malignancy arising in a nevus may give the first indication by a metastasis. Microscopically, they show a varying tissue of large or small cells in one part, and spindle or branched and stellate cells in other parts of the same tumor. The pigment is also a varying factor, being very dense in some portions and almost lacking in others. Melanin consists of fine amorphous granules varying from golden brown to inky black. It is soluble in ether, alkalies, and strong acids, and is bleached by chlorin, peroxide of hydrogen, and potassium permanganate. The question whether it originates in the cutis or epidermis, or both, and whether or not it is derived from the blood, has been raised and varying views expressed, but its blood origin is not supported by chemical examination, as it contains sulphur instead of iron. The view that it is due to an accumulation of nuclear substance and its conversion into pigment is held by several authorities. The real causation is still unknown. Most cases begin after the age of thirty, though it may occur earlier. They seem to be more common in the lower animals and not so malignant.

Animal Experimentation.—M. J. Rosenau shows the value of animal experimentation in the diagnosis of disease and cites a number of disorders in which it is essential. First, as regards tuberculosis, in which we have often to resort to animal experimentation in order to establish the early diagnosis which is requisite for successful treatment. The sacrifice of one guinea pig will often save a human life by the recognition of the disease. In typhoid the ultimate recognition of the typhoid bacillus depends on the use of the specific agglutinins. These are usually obtained from the horse or the rabbit, and laboratories now use large quantities of the serum thus derived to enable the physician to make an early diagnosis of the disease. The only positive method of typhoid recognition rests on animal experimentation. With cholera it is the same story. It is impossible to recognize mild cases clinically, and bacilli carriers are common. A single one may infect a whole community, and for successful prevention the specific serum is an absolute necessity. In rabies, the early diagnosis is life saving, and neglect fatal. The more experienced one becomes in the diagnosis of this disorder, the more does he depend on and recognize the value of animal experiments. In plague, the diagnosis of the disease with certainty is constantly being made by this method, and is indispensable. The preventive measures are entirely based on it. In diphtheria and tetanus it is often useful, as there is a whole group of organisms closely resembling the diphtheria bacillus, and their true nature cannot be determined without experiments on animals. The shape and growth of the tetanus bacillus is not sufficiently characteristic to be final. Other diseases mentioned in which this method is often required are septicemia, glanders, anthrax, etc., and a large class of animal parasitic disorders.

Aplasia of the Uterus.—C. L. Patton reports two cases of this defect, one of which is unusual in the following particulars: With a clinical aplasia of the uterus there was entire absence of the cervix, but the tubes or the body of an extremely small didelphic uterus opened directly into the vagina, and the ovaries were apparently normal in size and position. Menstruation was normal in amount and regular, without pain; the patient consulted the physician for a pseudocyesis, and examination revealed the above conditions. He remarks that he finds no such case exactly in the literature at his command.

Arteriosclerosis.—A. G. Brown summarizes the treatment of arteriosclerosis substantially as follows: In the early arterial stage a strict diet, regimen, and antitoxic treatment, consisting in elimination, intestinal disinfection, diaphoresis, and diuresis. When hypertension persists, the nitrites and iodides should be given, the latter in effective doses, and kept up for a given length of time. When the blood pressure has become lowered, the intoxication relieved, the kidneys act normally, and the symptoms of arterial spasm disappear, the patients may be considered cured, though a careful observance of the prophylactic regimen must still be kept up. In the cardioarterial stage, a permanent cure is not to be expected, but much can be done to relieve symptoms and to ward off a grave termination. Relief of symptoms, elimination of intoxicants and stimulation of kidney activity are the chief indications. This is accomplished by catharsis, followed by nitrites, spartein sulphate, etc. With the tension lower and the skin, bowels, and kidneys active, and diet carefully regulated, the use of nitroglycerin, erythrol, tetranitrate, potassium of sodium iodide, thyroid extract, and general medical supervision, the disease may be arrested and the serious accidents forestalled. In the myovalvular and cardiectatic stages, which merge into each other so as to form one continued progress to broken compensation, with dilatation of cardiac cavities and frequently orifices, lowered arterial tension, more or less visceral congestion and edema, and dropsy, are to be treated with the digitalis group, theobromin, interdiction of salt intake, restriction of diet to milk, and careful elimination of fluids. In these cases, often appearing hopeless, much can be done to restore the patient to modified activity, and the subject offers a field for the skill of the best powers of physicians.

Mesoaortitis.—W. T. Longcope says that during the past few years attention has been directed at the Pennsylvania Hospital to the frequent association of a peculiar type of arteriosclerosis, namely, mesoaortitis, with a chronic aortic endocarditis causing aortic insufficiency. For some years mesoaortitis has been recognized by German pathologists as a unique form of arteriosclerosis and its connection with syphilis emphasized. In 930 autopsies at the Pennsylvania Hospital, 21 cases showing this condition of mesoaortitis were observed, and in rather more than half its association with syphilis was proved. In all but three of the subjects there were definite signs of aortic insufficiency during life. While in a few of the cases a history of rheumatic fever was obtained, its absence in the series was rather conspicuous. The cases were compared with 76 cases of chronic aortitis also

found in the 930 autopsies, and the differences are pointed out in detail between the two classes of cases, especially the frequency of the combination of aortic insufficiency and mesoaortitis. This shows that of the 43 cases of true aortic insufficiency giving symptoms, 18, or 41.8 per cent., were associated with mesoaortitis, and of the 22 cases of aortic insufficiency uncombined with lesion of any of the other valves, 81.5 per cent. were associated with mesoaortitis. In his summary, Longcope says that it may be seen that aortic insufficiency unassociated with disease of the other valves is rare after the fifth decade, and that it is seldom associated with the type of arteriosclerosis known as endarteritis deformans. The majority of cases are associated with a characteristic form of sclerosis termed mesoaortitis. The involvement of the valves occurs probably under such circumstances by a direct extension of the process along the aortic wall to the aortic valve. Syphilis is commonly the cause, though it may not be the only cause, of this type of sclerosis.

The Lancet, January 1, 1910.

Postural Albuminuria in a Boy the Subject of Chorea.—This form of albuminuria was named by Stirling, who called attention to the fact that the most constant factor in albumin in the urine in apparently healthy persons is the upright position. After references to the experience of various authorities, J. S. Bury and J. F. Ward relate the history of a boy of twelve years admitted to hospital with chorea. He had previously had diphtheria and grippe. Movements of a choreic nature had begun four months previous to admission. He was placed on the arsenic and iron treatment, and the movements came to an end. He was allowed up, and then it was noted that the urine, before normal, contained albumin. He was put back to bed and kept on a milk diet, when the albumin disappeared. A second attempt at getting up resulted as before. Return to bed caused the albumin again to disappear. Several subsequent attempts at getting him up were always followed by the reappearance of the albumin. While he was still in bed, artificial lordosis was produced by placing a doubled-up pillow under his loins and removing those beneath his head. In ten minutes the urine, before previously free from albumin, contained it. Repeated attempts with the artificial lordosis resulted variously, albumin sometimes following and sometimes not. Treatment was continued with arsenic and iron, and massage and electricity to the legs. The boy left the hospital in about two months, greatly improved in health. His face was still pale, but he was fatter and could walk much better. There were no grounds for suspecting that the association of the chorea and albuminuria was otherwise than accidental. With regard to the possibility of nephritis, the only evidence was the puffy face with the history of diphtheria and influenza. Apart from the albuminuria, the urine was perfectly normal.

Treatment of Wounds in Connection With the Recent Results at St. George's Hospital.—Watson Cheyne says that it is most unfortunate that the idea seems to have grown up that the success or non-success in the treatment of wounds depends to a large extent on the materials used and on the method by which the sterilization of these materials is effected. Hence, when we fail in our methods the blame is assigned to the imperfection of these methods, whereas it is due to the failure of the surgeon to meet the bacteriological requirements of the case. All wounds should be looked on as bacteriological problems and treated accordingly. The attempt to establish strict aseptic methods, so-called, has met with many failures. Surgeons strain at gnats and swallow camels. He refers to the recently published statistics at St. George's Hospital, and shows that at King's College, where the equipment is far inferior to that of the other institution, sepsis occurs only one-quarter as often. In eight years at King's College, 1,028 cases of various nature were operated on and sepsis occurred only nineteen times. Particulars of the nineteen exceptions to the general result are briefly referred to. The author has been particularly free in his work from so-called stitch abscesses. There is still to be learned by some operators that there is a great deal more in the treatment of wounds than simple cleanliness and the avoidance of irritation. Each surgeon should take the view that suppuration in clean wounds is avoidable, and that the way to avoid it is to look on the treatment of a wound as a bacteriological problem and to act accordingly. Asepsis depends somewhat on the personal equation. Some of the author's house surgeons had no sepsis during their term of service.

Some Points in the Clinical History of Pneumonia.—Percy Kidd relates the histories of twenty abnormal cases. They include initial abdominal pain, particularly common in young children; initial symptoms of meningitis, initial hemoptysis, observations on fever and physical signs, abortive type with crisis on the second day, complications, laryngitis, nephritis, anasarca of renal type without albuminuria, etc. Various types of delirium are met with as well as diarrhea, and death from pulmonary embolism during convalescence. Typhoid fever may begin with pneumonia, and the latter disease may be combined with rheumatic fever, both infections being simultaneous. There may be relapsing types, though true relapses are very uncommon. Delayed resolution and subsequent fibrosis are occasionally seen. These latter conditions may be roughly divided into two groups. In the first the disease is febrile, terminating fatally, as a rule, in a few months. In most cases ulcerative cavities in the lungs develop, and the sputa may become foul. In the second group fibrosis occurs insidiously, arising out of what seems to be delayed resolution, without fever or constitutional disturbance, and the patient recovers with a fibroid lung. The cases described by the author variously illustrate the abnormalities enumerated, and furnish very interesting reading. Complications, he says, are mostly the expression of a secondary infection with streptococci and other organisms. True mixed infections, in which the pneumococcus and some other organism invade the system at the same time, are very rare. In other cases pneumonia attacks people already suffering from some other infection, and must be regarded as itself a secondary infection. The *râle redux* is in the author's experience of rare occurrence. Its absence throws doubt on the alveolar origin of crepitations. It seems more likely that it is produced in the small bronchi.

The Mechanism of Infection in Tick Fever.—W. B. Leishman says that he is an advocate of the theory of the protozoal rather than of the bacterial nature of the organism causing this disease. He has succeeded in transmitting the disease to animals by means of ticks sent to him from Africa. He was not at first able to discover spirochetæ in the bodies sent him, but later was able so to do. In some of his examinations he was able to discover clumps of chromatin granules in the malpighian bodies. The probable mode of infection is through the medium of the secretions voided by the tick in the act of gorging on the blood of the victim and not, as usually supposed, by the direct inoculation of spirochetæ in the tick's venenosalivary secretions. Other factors are the temperature at which the ticks have been kept prior to their being allowed to feed. According to the author, this preliminary heating up to blood temperature, as is commonly done, has the effect of inducing certain changes in the granules which may be regarded as heralding their transformation into the spirochetæ form. Two further facts are worthy of note: The author found, in the course of his experiments, that monkeys were comparatively immune. Secondly, he found on two occasions that there were clumps of the granules in the spermatozoa in the oviduct of an infected female. If this is the case, it suggests an interesting possibility as to the method by which the young intraovarian egg becomes infected, while it would not be unreasonable, on the grounds of analogy, to suspect that a similar procedure might occur in the case of the hereditary transmission of the *Treponema pallidum*.

British Medical Journal, January 1, 1910.

The Position of the Patients After Operation on the Abdomen.—S. K. Viner notes the various symptoms complained of by old abdominal cases from abdominal scars. He therefore calls the attention of celiotomists to the "rocking movement" as a postoperative therapeutic measure. Among its advantages are (1) the hustling of fluids which may be lurking in out-of-the-way holes and corners; (2) a discouragement of palsy of the bowel; (3) the hindering of the formation of bands and adhesions; (4) a generally sedative effect. A rolling motion is preferable to a pitching, and excess must be guarded against.

Efflorescence of Urea in Uremia.—J. W. Perevia refers to a man of 56 years who complained of dyspnea without apparent cause. Albumen was found in the urine. Two years later he had a cerebral hemorrhage, and a year later died of kidney disease. After death the skin of the forehead and nose was thickly covered with a coarse, white powder, which was collected and tested. Heated in a test tube, it gave off ammonia. The residue was heated with cupric sulphate and excess of sodium hydrate. It gave a rose color. The patient was under no treatment during the later months of his life, and the skin only exercised its excretory function with regard to urea in articulo mortis.

Presence of Bilharzia Hæmatobia in Egyptian Mummies of the Twentieth Dynasty.—Armand Ruffer has examined microscopically the kidneys of six mummies. The kidneys of two were apparently healthy. The left kidney of another was congenitally atrophied, those of the fourth contained multiple abscesses with well-staining bacteria and other lesions not yet diagnosed, while the fifth and sixth showed bilharzia eggs, and the latter had other lesions as well, which, owing to the shrunken size of the organ, were difficult to define. Although calcified, the eggs are easily recognized and cannot be mistaken for anything else. The lesions of bilharzia are best seen in the bladder and rectum, but, unfortunately, these are just the two organs the author has not been able to obtain thus far from mummies; various lesions as atheroma, pneumonia, renal abscesses, and hepatic cirrhosis are discernible in mummified viscera.

Defective Endocarditis Treated With Antidiphtherial Serum.—W. R. Judd gives the history of a man of 30 years with sweating, forcible pulse, hurried respiration, vomiting, headache, rigors, and fever. Examination of the heart on the third day gave evidence of a systolic murmur over the aortic valve, and on the fourteenth of a systolic murmur over the mitral valve. The urine contained albumin. Suppurative otitis was found in the left ear. By a process of exclusion a diagnosis was made of infective endocarditis. The patient was placed on large doses of quinine and arsenic, but they had no influence on the febrile movement, which reached 104° Fahr. The ear was cleansed, the alimentary and urinary tracts disinfected, etc., but all measures appeared unavailing. As antidiphtheritic serum had proved of utility in cases other than diphtheritic, an injection of 2,000 units was made into the abdominal parietes, and only one rigor, which the patient had been having frequently, took place during the next twenty-four hours. For the next five days there were no rigors and scarcely any fever. On the evening of the fifth day there was another rigor, and the temperature again rose to slightly above its former limit. Another injection, this time of 4,000 units, was given, and he had the same night only a slight rigor and only a little fever. After this the patient improved. He had no more rigors, the temperature kept closely to normal, and the man made an uninterrupted recovery. He remained in bed six weeks and removed to a convalescent home. Examination made some three months after his illness had begun showed that his heart was clear, his anemia much less, and his gain in weight some eight pounds.

The Mechanism of Cardiac Pain.—Three clinical histories are given by O. May. His studies comprise an observation of fifty cases, in thirty-five of which, or 70 per cent., pain was present. The author believes that no mechanical theory explains the severe pain in some of his cases, but says that there is one factor which may be presumed to be present to some degree in all cases of heart disease, viz., some chemical change in the myocardium. The suggestion presents itself that the stimulus to the cardiac nerve endings may be a chemical one, some change or product of the disordered metabolism of the heart muscle. There is a general belief that those heart affections are most characterized by pain in which at autopsy there is most evidence of myocardial degeneration. Paroxysmal pain is in most instances without any corresponding change in the physical signs of the heart. Pain often results from exhausted contractility. In the light of our biochemical knowledge it is impossible to suggest what actual compound or compounds may be invoked as an adequate stimulus to the heart nerves. This conception of the mechanism of cardiac pain tends to bring it into line with other painful conditions, such as the cramp of voluntary muscles and the lightning pains of tabes. Some authorities believe that the latter are caused by the gradual liberation of chemical irritants from the degenerating posterior neurons. The author considers in some detail the distribution of the nerves to the heart muscle, but says there is a defect in our knowledge as to exact details of distribution. It has been shown that the peripheral part of the cut vagus exhibits negative variations corresponding in frequency with the rate of the heart beats—strong presumptive evidence that the vagus transmits afferent impulses even during the normal heart rhythm. Tenderness in the sternomastoid muscle has been looked on as a sign often elicited in patients with failing compensation. It is a clinical manifestation of these afferent cardiac impulses in the vagospinal accessories. This tenderness was present in thirteen of the fifty cases examined. The details of all his series have been published in the Archives of the Middlesex Hospital for October, 1909.

Deutsche medizinische Wochenschrift, December 9 and 16, 1909.

Spinal Anesthesia for Anesthetizing the Body at Large.—Th. Jonnesco describes in minute detail the technique of his method of spinal anesthesia, enumerates the classes of cases upon which it has been used, gives his results, and summarizes his article as follows: (1) My method of spinal anesthesia has two fundamental principles—the preferable location for the spinal puncture and the use of stovain with small amounts of strychnine added to it. (2) The puncture of the arachnoid space is safe in almost any part, and any resulting injury to the spinal cord has no effect. (3) The mediocervical puncture or injection is superfluous and dangerous. The mid-dorsal puncture is also unnecessary and difficult. The upper dorsal and the dorsolumbar punctures and injections are sufficient to produce anesthesia of all parts of the body. (4) The strychnine does not aid the anesthesia, but prevents the paralytic action of the stovain upon the medulla oblongata. To the use of strychnine is due the harmlessness of this method of spinal anesthesia. (5) Stovain seems to be the best anesthetic for the purpose. Other materials require further investigation. The stovain is always used in connection with the aqueous solution of strychnine. The stovain is not sterilized, as by sterilization it loses its activity. (6) One c.c. of the watery stovain-strychnine solution is injected. A syringe and a lumbar puncture needle are used. (7) This spinal anesthesia has no contraindications, and it develops immediately when the anesthetic is injected into the arachnoid space and the dose is sufficiently large. (8) This method of spinal anesthesia has had no fatalities, and causes no discomfort. (9) Chloroform narcosis is inferior to the present method of spinal anesthesia, as the latter may be applied with perfect safety with any patient, makes an assistant unnecessary, immobilizes the head, neck, upper and lower extremities, and the intestines, and is especially favorable for operations in these regions. As a rule, one uses light chloroform anesthesia for operations on the neck, face, and head, and movements of these parts interfere with the surgeon.

The Treatment of Syphilis with Quinine Preparation.—Lenzmann gives a second report on the use of quinine in syphilis. He calls attention to the fact that in certain cases mercury and the iodides cannot be taken. He concludes that, on the grounds of his experience, that as the etiological factor of syphilis sooner or later becomes refractory to the poisons which act upon it, it is necessary in the course of a syphilis cure to use various of the agencies which act upon the exciting cause of the disease. The first means to be used is mercury. Afterward, however, potassium iodide and quinine come into play. The indication for renewal of treatment should not be determined by the presence of subjective or objective symptoms, but by a positive Wassermann reaction.

Potassium Chlorate in the Serodiagnosis of Syphilis.—Brieger and Renz have endeavored to simplify the complement deviation reaction of Wassermann by substituting some pure chemical substance for the amboceptor used by Wassermann, namely, rabbit serum immunized to sheep corpuscles. After various efforts they succeeded by using solutions of potassium chlorate, one part to physiological sodium chloride 150 parts. The complete technique consisted in the use of inactivated serum, watery and alchoholic solutions of syphilitic liver, and fresh guinea-pig serum for complement. After one hour for binding of the complement at 37° C. they added a 5 per cent. sheep corpuscle solution, and as the hemolysin, 0.5 to 1.0 c.c. of the potassium chlorate solution. The sera of 65 patients, both syphilitic and non-syphilitic, were studied, and of each serum five tests were made. Each was controlled by the regular Wassermann reaction, and in every instance the results agreed completely. The authors conclude by saying that many more observations are necessary for definite conclusions.

An Anatomical and Clinical Contribution on Parametritis Posterior Chronica.—Fraenkel concludes a lengthy article on this subject as follows: (1) The so-called parametritis posterior chronica consists of a change of the physical characteristics of the retrocervical and retrovaginal connective tissue, consisting of decrease in or the disappearance of the elastic fibers and muscle elements, especially of the sacrouterine ligaments. (2) It occurs as the main lesion once in every ten, and as a secondary condition once in every two, females suffering from genital diseases. (3) The diagnosis is made by the functional testing of the posterior ligaments. (4) For the differential diagnosis from perimetritis Douglasii the testing of the torsus uterinus must be done more than previously. (5) The cause is very often masturbation.

Book Reviews.

Über nichtdiabetische Glykosurien. Von Prof. Dr. Ferdinand Blumenthal, leitendem Arzt am Israelitischen Krankenheim zu Berlin. Halle a. S.: Carl Marhold Verlagsbuchandlung, 1909.

The writer has long been known as a chemist of large experience and the author of an excellent text-book on the analysis of the urine. With these qualifications, it was to be expected that the little pamphlet on the glycosurias not connected with diabetes would be full of interesting matter. The discussion includes alimentary, infectious, and toxic glycosurias, a chapter on the very infrequent levulosurias, another on the appearance of lactose in the urine, and a chapter on pentosuria, neglecting, as usual, the American publications on the subject. The final chapter is one on the testing of the urine for sugar, and, while somewhat condensed, contains most of the important points.

Selected Papers on Hysteria and Other Psychoneuroses. By Prof. Sigmund Freud, Vienna. Authorized translation by A. A. Brill, Ph.D., M.D., Chief of Nervous Dispensary, Beth Israel Hospital; Clinical Assistant, Department of Psychiatry and Neurology, Columbia University; Assistant in Mental and Nervous Diseases, O.P.D., Bellevue Hospital; Assistant Visiting Physician, Hospital for Nervous Diseases. New York: The Journal of Nervous and Mental Disease Publishing Company, 1909.

The reviewer ventures the remark that the readers of Freud, in the original, in this country, are few in number. The subject-matter and the German are too difficult for most of us. A translation of representative papers by him, outlining his views and methods, is therefore welcome. The book is divided by the translator into ten chapters. In the first the author describes the psychic mechanisms of hysterical phenomena, and we learn at the outset that the hysterical symptom has a definite meaning, that it is a reminiscence of a former painful or disagreeable experience. The second and third chapters contain interesting analyses of a number of cases of hysteria. The three succeeding chapters treat of the neuroses and psychoneuroses, while in the final chapters may be found especially Freud's views respecting the rôle of sexuality in the neuroses. If a careful perusal of the book does not at once make the reader a Freud convert and enthusiast, it will at least imbue him with renewed hope regarding the prognosis of some cases of chronic hysteria, obsessions, and phobias hitherto looked upon as practically hopeless. The keynote of the Freud papers is individual psychology. He writes as if confident that he has solved the riddle of the neuroses. The translation meets every requirement.

Medical Diet Charts. Prepared by H. D. Arnold, M.D., Professor of Clinical Medicine at Tufts Medical College, Boston. Philadelphia and London: W. B. Saunders Company, 1909.

The general practitioner will find these diet charts useful in regulating the diet of his patients. They give on one sheet all the data necessary for arranging and calculating the nutritive value of a diet and furnish a convenient means of recording the results. Chart A has space for recording the diet for five successive days or for five changes of diet for any interval of time. Chart B fulfills the same functions for a single day. The charts also give information as to the nutritive value of food in measures such as are used in everyday life.

Surgical Diagnosis. By Edward Martin, M.D., Professor of Clinical Surgery in the University of Pennsylvania. Illustrated with 445 engravings and 18 plates in colors and monochrome. Philadelphia and New York: Lea & Febiger, 1909.

Of the nineteen chapters in the book, the first five deal with general subjects, the next six with the various tissues of the body, and the last eight with regional surgery. The chapter on laboratory diagnosis is written by Dr. Warfield T. Longcope; that on *x*-ray diagnosis by Dr. Henry K. Pancoast; that on gynecology by Dr. Brooke M. Anspach; that on nervous diseases by Dr. Theodore H. Weisenburg; and that on diseases of the eye largely by Dr. George E. de Schweinitz. The value of calling in the assistance of experts in special lines is apparent. The book is concise, exact, and practical. The author leaves no misunderstanding of his meaning. For instance, on page 454 he says: "Pericardial blood effusion following a wound immediately or shortly (hours) or developing suddenly later (days) is almost pathognomonic evidence of heart lesion." This method of statement is used frequently. A mine of information is often contained in a page. In describing the esophagus, for instance, the author gives its location, size, etc., in a few words, and tells precisely how to explore it. He is guilty of no exaggeration when he says: "Dr. Pancoast's outline drawings of negatives in his possession constitute the most complete series of *x*-ray fracture pictures yet published." They are remarkable for their clearness, accuracy, and number. The other illustrations of the book are also good.

The Ophthalmic Year Book. Volume VI. Containing a Digest of the Literature of Ophthalmology, with Index of Publication for the Year 1908. By Edward Jackson, A.M., M.D.; Professor of Ophthalmology in the University of Colorado; George E. de Schweinitz, A.M., M.D., Professor of Ophthalmology in the University of Pennsylvania; Theodore B. Schneideman, A.M., M.D., Professor of Ophthalmology in the Philadelphia Polyclinic. Illustrated. Denver, Colo.: The Herrick Book & Stationery Company, 1909.

The conception of the "Ophthalmic Year Book" was a happy one, since its realization places an annual epitome of all that is of value in ophthalmological literature before the reader in a form which renders it easily accessible. In addition, it gives a comprehensive bibliography of the yearly writings in this branch of medicine, which is of great value to the student. The present volume is an improvement on its predecessor. No progressive ophthalmologist can afford to be without it.

Miner's New Complete Obstetric Record, Combining with the Usual Record All Desirable Medical Statistics; together with a Medical History of the Pregnancy and of the Life of the Child whenever these are medically noticeable. Improved Edition, giving all medical data bearing upon the problem of heredity. Ann Arbor, Mich.: Joel A. Miner, 1909.

The reviewer sees no advantage in the "Obstetric Record" over the book provided by the local health boards in cities where such a book is published. If additional records are required, they may be kept on cards and filed away for future reference. For country practitioners it will be found very useful.

Organic and Functional Nervous Diseases. A Textbook of Neurology. By M. Allen Starr, M.D., Ph.D., LL.D., Sc.D.; Professor of Neurology, College of Physicians and Surgeons, the Medical Department of Columbia University, in the City of New York; Consulting Neurologist to the Presbyterian and St. Vincent's Hospitals, and to St. Mary's Free Hospital for Children; ex-President of the American Neurological Association and of the New York Neurological Society; Corresponding Member of the Société de Neurologie and of the Société de Psychiatrie de Paris, and of the Neurological Section of the Royal Society of Medicine, London. Author of "Familiar Forms of Nervous Diseases," "Brain Surgery," and "Atlas of Nerve Cells." Third Edition, thoroughly revised. New York and Philadelphia: Lea & Febiger, 1909.

The popularity of the second edition of Starr's book, wherein a section devoted to functional nervous diseases had been added to the original work, is attested by the fact that it was published but two years ago and has become exhausted in this time. The present edition is considerably enhanced in value by the addition of many new engravings and plates, notably those in connection with the presentation of new pathological material; and by much revision, some rearrangement, and additions to various parts of the book. The structure of the nervous system and principles of diagnosis and localization are brought together in the first part; organic diseases are discussed in part two; functional diseases in part three; and diseases of the sympathetic system in the last part. Comparison of this edition with the previous one shows noteworthy revisions of the chapters on tabes, syphilis, paresis, neurasthenia, hysteria, psychasthenia, epilepsy, and the vasomotor and reflex neuroses. Advance knowledge in regard to various diseases has been incorporated in a conservative way; for example, in regard to decompressive operations in diseases of the brain; in the discussion of nerve grafting, the treatment of mental states, the description of diseases but lately understood and recently described, etc., the author's personal observation and experience have been so great in clinic, hospital, and private practice that he is enabled to speak authoritatively from this standpoint. Frequent references are made, however, to important articles in the literature of the various subjects considered.

Society Reports.

SOUTHERN SURGICAL AND GYNECOLOGICAL ASSOCIATION.

Twenty-Second Annual Session, Held at Hot Springs, Va., December 14, 15 and 16, 1909.

THE PRESIDENT, DR. STUART MCGUIRE OF RICHMOND, VA., IN THE CHAIR.

A Brief Discussion of Some of the Surgical Junk, Demanding Further Surgical Interference.—Dr. JOSEPH PRICE of Philadelphia stated that a short time ago a patient entered his office, and asked him to reopen her abdomen, and to correct, if possible, a distressing condition that she could bear no longer. Her abdomen had been opened three times, a pelvic operation having been followed by two gall-bladder operations. She complained bitterly of a griping sensation in her epigastric region, followed by nausea and starvation. In a short period of six days he had reopened four abdomens for post-operative, pathological and operative sequelæ. Large numbers of these patients were objects of pity and mercy. One of the number had had her abdomen opened eight times. Fortunately the late operations were complete procedures, the reproductive organs and appendix were gone, leaving only a ventral hernia, omental and bowel adhesions to be freed. One of the late operators drained her gall-bladder, leaving a fistula and distressing adhesions. He liberated the stomach, bowel, and other adhesions, exposing the gall-bladder, disorganized and charged with pus; its clean removal would probably result in a cure. Dealing with surgical junk required more than the ordinary hospital apprenticeship. The operations done by pioneers in abdominal surgery were free of operative sequelæ. The percentage of recoveries was good in the country. He had had the opportunity of seeing a large number of the patients operated upon by the first school of abdominal surgeons. They constituted an interesting group of patients, none of them complaining of those common symptoms of modern operations. The high death rate in the hands of some few operators explained surgically the distressing condition of the few that did recover, but commanded more surgery.

Dr. LEWIS S. MCMURTRY of Louisville said that Dr. Price had called attention to one of the greatest evils prevalent at this time in relation to abdominal surgery. He alluded particularly to incomplete operations being done and to a large number of men who were operating in the abdomen who ought not to do so without having served an apprenticeship in this work. When this association was first organized it was far more difficult for men who were not qualified to do abdominal surgery than at the present time.

Dr. A. VANDER VEER of Albany, N. Y., said he always felt that there was a certain amount of risk in encouraging abdominal surgery in small hospitals because much of the work was necessarily done by men who had not served a sufficiently long apprenticeship to do the work thoroughly and completely. Not infrequently a correct diagnosis was not made and incomplete operations were undertaken which did not reflect credit upon American abdominal surgeons. Within ten or fifteen years there had been a sort of feeling on the part of our younger surgeons to do as many operations as they could upon a particular patient. In this regard they sometimes erred. He had seen many cases that had terminated in what Dr. Price had termed surgical junk. He appreciated this paper because it was not only timely, but it dealt with a subject to which more attention should be paid at the present time. It was the kind of paper for the younger surgeons to read carefully.

Dr. WILLIAM M. POLK of New York City stated that the trouble with some of us was that perhaps we had been endeavoring to work out pathological problems on live subjects and in so doing we might have left conditions within the abdomen in our endeavor to preserve structures, and so forth, that really had no business there. And in so far as he had been a sinner in that direction he was free to confess that probably he deserved all the criticism that the distinguished essayist had made. He was particularly obliged to him because in his paper he opened up the whole field of surgical work. He found that the average person had been so well educated that his or her mind was made up as to what they wished their physician to do long before they interviewed them and if he failed in any way to fall in with their preconceived notion they at once went elsewhere. We all know perfectly well that there was a great many of the younger members of the profession who had not that stiffness of spine that comes with age, that kind of ankylosis of the vertebral column which was beneficent in its influence and which did come with age and experience.

Adhesion of Sigmoid to Tube and Broad Ligament as a Cause of Pain in Salpingitis.—Dr. HUBERT A. ROYSTER of Raleigh, N. C., reported the following case: Mrs. S., 32 years old, married seven years, had given birth to one child about a year before. Previous to that she had had an abortion performed on account of pernicious vomiting. Several weeks before he saw her the same procedure had been again gone through with for the same reason. For two or three years she had suffered from typical tubal dysmenorrhea, the pain began a week before the flow and continued throughout the period. Intermenstrual pain was constant, and referred chiefly to the left iliac region; there had been several slight attacks of pelvic peritonitis. Defecation was particularly distressful. Almost every day the patient took morphine or heroin. Examination revealed extreme tenderness in either side of the pelvis, especially in the left. A diagnosis of chronic salpingitis was made. At operation, March 28, 1907, both tubes, tortuous and thickened, were removed. Their removal was considered justified in view of the history. The ovaries were what are called "cystic." He removed the left and excised two-thirds of the right one. In bringing up the left tube for inspection he found that the sigmoid flexure was adherent to its fimbriated end, and also to the upper surface of the broad ligament. These adhesions were carefully divided, and the raw areas were closed by fine catgut sutures. The result was all that could have been expected. The patient immediately improved, but not until six months had passed was she really relieved. She was now entirely well, menstruating regularly without pain. The speaker had records of eight similar cases in which the sigmoid adhesion was apparently the sole source of left-sided pelvic pain. He was convinced that the condition was one to be reckoned with. In association with salpingitis or other disease of the pelvis could not, as a rule, be determined beforehand, but it might be suspected in the absence of other lesions, to account for the suffering and more especially in the presence of painful defecation. This had been a constant symptom in the instances which he had observed.

Dr. HENRY T. BYFORD of Chicago said that when a patient presented herself with pelvic disease he always asked her whether she had pain or not on defecation. Then he asked the question, do you have any mucus in the stools? He thought we frequently found mucus in the stools in such cases, but not the abundant mucus which comes from a general colitis, nor the tendency to tenesmus with mucus, that comes from inflammation low down in the rectum. There was pain on defecation, particularly when these patients were at all constipated, and there was mucus in the stools. In connection with the symptoms, if the pain was in the iliac region there would be found adhesions to

the sigmoid flexure. In another class of patients there was pain in the back, and no pain in the iliac region.

Dr. Robert T. Morris of New York said there was one place where the surgeon should allow adhesions to remain, namely, in his subliminal mind. There was no one thing more often overlooked in his experience than peritoneal adhesions, and their influence. Dr. Royster liked to close raw surfaces by continuous sutures. They saved time by one of two methods. The commonest one which he had used was to sprinkle aristol over the raw surface and wait until lymph accumulated and engaged the aristol in a mesh. This acted as an obstacle to further adhesion and he had found it satisfactory in his experience on animals. The other method was to use sterilized animal membrane. That took a little longer, but in such cases as Dr. Royster had described aristol powder would engage itself in the lymph coagulum, and present an excellent mechanical obstacle to readhesion.

Dr. Thomas S. Cullen of Baltimore said he had a patient at the present time who had complained for five or six years of severe constant pain in the left side. On opening the abdomen he found the uterus perfectly normal. The tubes and ovaries showed no alteration. There was no thickening of the ureter. In making a closer examination of the sigmoid he found it adherent to the entire left broad ligament, extending as far forward as the round ligament. He adopted a procedure similar to the one described by the author of the paper, that is, freeing the adhesions as thoroughly as possible, and closing the raw surface of the broad ligament by a continuous catgut suture, and the raw surfaces of the rectum by interrupted suture, on account of which slight tearing was not so likely to occur.

Dr. I. S. Stone of Washington, D. C., said that in opening the abdomen for tuberculous peritonitis and allied conditions they could never hope to separate all adhesions in such cases. It would be folly to try to do it. There were many women who had extensive adhesions, one organ being thoroughly adherent to its fellow, yet there might be no pain on defecation, or pain at any time. Where were they to stop in separating adhesions when they had such cases as that? He found he was getting excellent results from operating upon patients and placing the bowels in the very best condition he could for continuous passage of flatus and feces. He had separated adhesions of the sigmoid and in some cases had been astonished to find not only the greatest improvement, so far as pain and local distress were concerned, but in the general improvement of the patient, when the sigmoid had been sutured up out of the pelvis, where there should be continuous passage of flatus and gas, instead of more or less obstruction, produced by a circular folding or duplication of the sigmoid in the pelvis. Such an operation as that had given him more comfort than the mere separation of adhesions.

Dr. W. P. Carr of Washington, D. C., said it was the situation of the adhesion and not the extent of it that caused trouble. A patient experienced great pain where there was a slight, strong adhesion attached to a small area of some movable organ; whereas in the case of an extensive adhesion to a large surface the weight was sustained without any pain whatever. The most painful adhesions had been those where there was a small band pulling on some point of a movable organ.

Dr. Royster, in closing the discussion, said that he was very glad Dr. Byford mentioned the discharge of mucus, because that was very important. The question then arose, in such a case was not intestinal condition the cause of adhesion rather than the pelvic disease? Where the adhesion was due to intestinal stasis the discharge of mucus was a prominent symptom, but where it was secondary to pelvic disease, mucus was not a prominent symptom.

The Treatment of Advanced Extrauterine Pregnancy.—Dr. Reuben Peterson of Ann Arbor, Mich., in his paper drew the following conclusions: 1. Whenever conditions permit operation for the removal of the gestation sac is indicated in the first half of an extrauterine pregnancy since, at this period, the mother is in great danger from rupture and sepsis, and the chances for the survival of the fetus are very poor. 2. During the latter part of an extrauterine gestation the chances of rupture and a fetal hemorrhage are very much less (4.8 per cent.) and the chances of the survival of the fetus are very much greater. 3. While malnutrition and malformation of the extrauterine child are more common than with the fetus under normal conditions, they are not frequent enough to contraindicate attempts at saving its life; hence, under favorable surroundings when the patient can be watched she should be allowed to go within two or three weeks of term before operation. 4. Since the maternal mortality is more than twice as great after operation in advanced extrauterine pregnancy where the placenta is left behind, its removal should be one of the cardinal principles of each operation. 5. In the discoid variety of placenta, where only a small surface of this organ is not attached, the blood supply must be controlled, either by tying the vessels, or by compression of the aorta before an attempt be made to remove the placenta. 6. When, for any reason, removal of the placenta is impossible, the sac should be stitched and the placenta shut off from the peritoneal cavity by gauze. 7. Dependent drainage through the vagina should be secured whenever possible.

The Advantages of Neglect in Appendicitis Operations.—Dr. Robert T. Morris of New York said surgeons had conscientiously tried to do too much in appendicitis operations and had damaged patients unnecessarily. According to the principles of the pathological era in surgery they felt bound to remove all the products of infection in a most thorough way. They made elaborate arrangements for drainage, and they took the greatest care to avoid infection of the normal peritoneum. All of these things which they did with so much care and caution were commendable until they learned to step over to the principles of the fourth, or physiological, era in surgery, allowing the patient to do most of the work of managing infection himself. Their function to-day was merely to turn the tide of battle, and to place the patient in such condition that he could call out his own resources and fight the battle better than they could do it for him.

Dr. Joseph Price of Philadelphia said he wanted to condemn unqualifiedly stump operations of every character, for the reason that they were too far advanced to leave one-sixth or one-eighth of the appendix when operating for appendicitis. A clean removal of the appendix was a simple procedure.

Dr. W. P. Carr of Washington, D. C., said Dr. Morris was certainly right in one respect, namely, that in the bad cases of appendicitis they must fit the operation to the condition of the patient. He had seen many patients recover after a simple opening had been made, and pus let out, nothing further being done except perhaps to put a catgut ligature around the appendix and remove it, if it is possible to do so at the time. Such patients would not have stood a prolonged operation.

Dr. J. M. T. Finney of Baltimore wished to take exception to the word "neglect" in the title of Dr. Morris' paper, and ventured to suggest in its place the word "observance," meaning by that observance of certain fundamental principles of surgery.

Unusual Type of Bladder Tumor.—Dr. Robert C. Bryan of Richmond, Va., reported briefly a cavernous angioma of the bladder. By suprapubic cystotomy the tumor was located with difficulty, owing to the collapsed condition of the bladder. With serrated scissors it was carefully dis-

sected out of the mucosa, the base was thoroughly seared with the Paquelin cautery, the free edges of the mucous membrane were now stitched together with catgut, the bladder sewed to the abdominal wall, and drainage established. There was little hemorrhage. The patient reacted well and made a good recovery. The tumor measured about ⅜ of an inch in diameter.

Observations Upon the Surgery of the Knee-Joint.—Dr. J. Garland Sherrill of Louisville stated that fracture of the patella might be a very simple injury, if the fracture was incomplete and the fragments were not separated. On the other hand, a compound fracture of this bone became a most serious accident. The result, after the so-called expectant treatment of fracture of this bone, might be sufficiently good to insure fair functional use of the limb. The results of the open operative treatment, however, were so much better that in healthy young patients and under proper surroundings the open method was strongly to be advised. He recorded a case in which first one and then the other patella was dislocated as result of trauma, with a persistence of dislocation in each case. The operation for its relief consisted of an incision on the inner side of each knee through the quadriceps tendon, and the edges of this muscle were overlapped so as to shorten the attachment of the patella on the inner side, according to the mehod described by F. E. Bunts. Dislocation of the semilunar cartilage proved very troublesome to the patient and frequently caused great pain, as well as fixation of the joint. The internal cartilage was affected more frequently than the external, and the dislocation might be partial as a folding of the cartilage upon itself, or the entire cartilage might be separated. The causative factor was in most cases a sudden torsion of the tibia, although a blow driving the tibia backward in moderate flexion might produce it. The diagnosis was to be made by the sudden fixation of a previously healthy joint, accompanied by a sharp pain, with subsequent restoration of function, and later a recurrence of the symptoms. Effusion into the joint might follow the injury and in some cases the cartilage might be felt in front of the joint near the margin of the tibia. Pressure over its former attachment would elicit pain and soreness. The latter was a valuable point in the diagnosis of this condition from loose (extraneous) bodies in the joints. Treatment for this condition was either palliative or operative.

Dr. A. R. Shands of Washington, D. C., said he had no more hesitation in opening the knee-joint than he would have in opening the abdomen, and he had been doing it right along in cases of obstinate synovitis. In many cases of recurrent synovitis the joint had never been emptied of synovial fluid. The accumulative synovial fluid formed a mass similar to that in the bottom of an old vinegar barrel, and that was what caused recurrence of the trouble.

Dr. W. O. Roberts of Louisville said he agreed with Dr. Sherrill relative to the treatment of fractures of the patella, in that he had long since given up the use of metal appliances for holding fragments together. He resorted to the open method in the treatment of these cases where they had the advantages of a suitable infirmary. He had seen but two cases of dislocation of the patella.

Dr. Horace J. Whitacre of Cincinnati said he wished to report two cases of loose semilunar cartilage, one in a boy ten years of age, in which the cartilage was organized and was removed; the other in a patient in whom the cartilage seemed to be in fairly good shape, and was sutured in place. The boy remained in good condition except that he had had some pain from time to time when he exerted himself, but he had had no further displacement.

Dr. John C. Wysor of Clifton Forge, Va., recalled one case in which he found fifteen floating bodies in the knee-joint, which ranged in size from the size of the end of his little finger to more than an inch in diameter. Operation was followed by a good result.

The paper was further discussed by Dr. Stephen H. Watts of Charlottesville, Va., and Dr. Randolph Winslow of Baltimore.

Myositis Ossificans Traumatica.—Dr. J. M. T. Finney of Baltimore said the pathological condition which formed the basis of his paper was one, the existence of which had been recognized for a long time, but only within a comparatively few years had it attracted any general attention. Including the seven cases reported in the paper, over 150 cases now have been so far recorded. There was always danger of mistaking this disease for sarcoma. Three of his cases came to him with a provisional diagnosis of sarcoma of the femur. There still existed a considerable difference of opinion as to the manner in which these bony deposits took place, and the source from which they came. He called attention to a number of distinct conditions which had been grouped under the general head of "myositis ossificans." These all represented different pathological processes. The factor most concerned in the production of this trouble was unquestionably a single severe trauma, as, for instance, a kick by a horse. Nearly one-half of all the cases were observed in the front of the thigh, involving the quadriceps extensor muscle. This and the flexor muscles of the arm seemed to be the most common sights. The symptomatology was, as a rule, quite characteristic. Following a severe trauma there might be noticed the usual clinical phenomena, namely, localized swelling, tendnerness, ecchymosis, and disturbance of function. As prophylactic measures, aspiration and pressure were of somewhat doubtful efficacy, although highly recommended. Early incision with the evacuation of effused blood, the thorough removal of small fragments and spicula of bone, with drainage of the affected area may, in some instances, prevent the formation of the trouble. Massage in the early stages was contraindicated, as it might affect unfavorably the development of the trouble by stimulating the production of bone. The indications for operation were the presence of the tumor, the disturbance of function, pain, etc.

Cholecystenterostomy in Certain Cases of Pancreatitis.—Dr. Le Grand Guerry of Columbia, S. C., made a plea for the more general use of this operation in this disease. He related a case which was typical of quite a number to serve as a concrete illustration. Mr. M., aged 38, married, several years ago had an attack of pain in the gall-bladder region, with very slight jaundice, pain occasionally radiating under the right shoulder, slight fever, indigestion, etc. These attacks occurred at infrequent intervals, but there was a gradual weakening and loss of flesh. There was no sugar in the urine. A diagnosis of gallstones or pancreatitis or both was made and at the operation a slightly distended gall-bladder, with no stones, was found. The bladder was full of the characteristic ropy, tarry, black bile and a well-marked colon bacilli odor to it. The pancreatic head was markedly enlarged. Operation consisted in cholecystotomy after the common duct had been thoroughly explored and a probe passed into the duodenum to insure the patency of the choledochus. Drainage was continued for three months, during which time the patient gained twenty pounds in weight and was completely restored to health. Later the patient had another attack, at which time cholecystenterostomy was done, with the result that he had been permanently relieved from all of his symptoms and was now in perfect health.

Pancreatic Hemorrhage and Acute Pancreatitis.—Dr. Joseph Ransohoff of Cincinnati reported three cases, two of the former and one of the latter. They were all of the ultra-acute type. In two of the cases the hemorrhage into the free peritoneal cavity was very extensive, so

that one might have thought of the rupture of one of the large vascular viscera or of a large mesenteric vein. In the third case the fluid was only tinged with blood. In two of the cases, where the hemorrhage was very severe, no fat necrosis was seen at the time of operation. In the third a fat necrosis led to the diagnosis during the operation. One of the acute cases with severe hemorrhage recovered after laparatomy with drainage and gauze packing. In one of the fatal cases, fat necrosis was not seen at the time of the operation nor after autopsy was made. In none of the cases was a diagnosis made. In one it was thought of on account of the slight jaundice which was present. In the critical part of the paper the time for operation and the method of procedure were considered. While, as in phlegmonous conditions elsewhere, it would seem necessary that the lesion of the pancreas should be attacked in every case from an academic viewpoint, it was not practicable in all cases. The condition of the patient was often so desperate that a prolonged search for the lesion would be fatal, while drainage and gauze packing properly placed would give the patient a chance for recovery. Statistics with great preponderance showed the value of attacking the pancreas in a formal way as part of the operative interference as compared with drainage alone. Statistics, however, could have little value in determining the procedure to be adopted when one considered the great variation which existed in the symptoms at the time an operation was performed. Each case must be considered on its own merits and the operator must know to what extent operative interference beyond drainage and walling off the focus of the disease with tampons the patient would tolerate. No fixed or fast rules should be laid down. In regard to chronic pancreatitis, he objected to the off-hand way in which a diagnosis was often made at an operation by the sense of touch alone and regardless of the existence of the well-known clinical evidence of chronic pancreatic disease.

Pancreatoenterostomy.—Dr. R. C. Coffey of Portland, Ore., stated that the drawback to the development of pancreatic surgery had been that during embryological development the pancreas had been rotated out of the peritoneum. The peritoneum produced an exudate when injured which served the same purpose as callous after a fracture. The fat splitting ferment of pancreatic juice did not readily penetrate the peritoneum, but was serious when spilled in the retroperitoneal areolar fat spaces or between the layers of the mesentery or omentum. The problem to be solved in direct pancreatic surgery was to supply peritoneum to the operative field. This was best obtained from the outer coat of the intestine by inversion. The lumen of a single intestine was too small. Therefore, it had been necessary to throw the two lumina of an intestinual loop into one which, after inversion, gave an ample peritoneal canal into which the cut end of the pancreas was implanted. Using this method the following classes of operations were done: The tail of the dog's pancreas was cut in two and each cut end implanted into a separate loop of jejunum. Of four specimens recovered, each showed perfect union between pancreas and intestine; but no pancreatitis nor necrosis. In isolating the tail of the pancreas the pancreatic duct was found patent and delivered into the intestine. The connected end of the pancreatic duct was closed by a thin, tough film, the juice all going through the duct of Wirsung. The same thing occurred where the duct was ligated by a linen ligature but not cut, for the ligature was circumvented in all cases, and the juice was freely delivered back into the duodenum through the duct which was established amound the ligature. By ligating and cutting both ducts of Wirsung and Santorini and interposing omentum, and implanting the cut end of the tail, the juice of the other tail and body was freely delivered into the loop of jejunum through the implanted tail and its duct maintained. Second, the head of the pancreas and one tail and the duodenum were successfully removed in two stages. *First,* the bile duct was transplanted to intestine lower down, and a gastroenterostomy done with excision of pylorus. *Second,* two weeks later the body and one tail of the pancreas and section of duodenum were removed and the remaining tail implanted into the jejunal loop. The results were the same as in the previous cases. In all five cases the specimen showed enormous dilatation of the common and hepatic ducts, and in one instance the bile duct was almost as large as the duodenum and almost as thick. The communication with the intestine was free enough to admit the end of the little finger, the distention evidently being due to intraintestinal pressure; therefore, an indirect method was devised, which consisted of running the duct immediately under the mucous membrane for an inch before bringing it inside. The results in the three specimens removed, two of which were of two months' standing, showed that a perfect valve had been formed and no dilatation had occurred, the ducts being entirely normal in size and thickness. Encouraged by these results the writer was now conducting a series of experiments in which the ureter was implanted into the large intestine in the same manner with the hope of preventing ascending infection here. Direct implantation of the stripped pancreatic duct was tried in six cases. While one dog lived to be killed on the 24th day and was in good health, it was found that the duct connected with the intestinal lumen only by a fistula. Four of this group of dogs died before the sixth day, showing pancreatic necrosis. One died on the tenth day. One fact stood out in all the six cases, namely, the pancreatic duct died as soon as it left the pancreas, thus leaving the inference that the pancreatic duct probably received most of its nutrition from adjacent pancreatic substance, and would not bridge the chasm between the gland and intestine, as was done in the case of the bile duct and ureter.

Dr. Joseph C. Bloodgood of Baltimore stated that the cause of death in acute hemorrhagic pancreatitis had been said to be due to trypsin and perhaps other ferments free in the peritoneal cavity, and present in the blood, and these ferments produced disseminated fat necroses. If one could make a diagnosis of acute pancreatitis the abdomen should be opened and the fluid allowed to flow out and the region of the pancreas drained to prevent further intoxication with these ferments. The question of the operative treatment of acute hemorrhagic pancreatitis was settled, and that was, evacuation of the peritoneal exudate and drainage of the pancreas.

Dr. Stephen H. Watts of Charlottesville, Va., said that during the present year he had had three cases of acute pancreatitis, one of them of the subacute variety. One of the most interesting things in these cases was the presence of hemorrhage in acute pancreatitis, and it was a question in his mind as to the relation of this hemorrhage to infection in the gland, as to whether or not hemorrhage preceded infection, or pancreatitis, or whether it followed it. Dr. Ransohoff had not found infection in his early cases, as the cultures had been negative. It looked as if in many of these cases there was an arteriosclerosis which might give rise to the first hemorrhage, and that the blood subsequently became invaded through the intestine or biliary tracts.

Dr. Roswell Park of Buffalo stated that at the time President McKinley was shot we did not know much about the surgery of the pancreas, and when seeking an explanation for the peculiar necroses which were found in his case, he suggested that in all probability the wound of the pancreas had to do with the subsequent course of events. He really believed that this wound of the pancreas had much to do with it. He believed that unfortunate instance directed surgical attention to the surgery of the pancreas

in a way which it would not have done had not that sad event happened.

Dr. Chas. H. Mayo of Rochester, Minn., said he was struck with what Dr. Guerry has said with reference to cholecystenterostomy. No doubt this operation should be more frequently done. If there was jaundice present, with hardening of the pancreas, and no gallstones, then we should at once think of the advisability of doing this operation. The question of doing it in simple inflammatory conditions, such as cholecystitis, was something for the future to decide. But these were not the gall-bladders that they would remove to-day, but they were the ones that led to further operation.

Dr. H. A. Royster of Raleigh, N. C., stated that two months ago a man, 70 years old, came in with a typical history of gallstones. He had had jaundice only once, and that had disappeared entirely. Examination of his urine three days before operation showed a well-marked reaction to sugar. They opened his gall-bladder, removed one hundred and eighty gallstones, and drained in the usual manner. The head of the pancreas was enlarged. One week after the operation the sugar disappeared entirely from the urine, and had not returned.

Dr. Walter C. G. Kirchner of St. Louis stated that of five cases of pancreatitis he had met with three which were of the suppurative type and resulted fatally. In two of these cases a diagnosis was made, but the conditions were so fulminating that opertaive procedure did not seem to be indicated, or by the time the patient reached the hospital his condition did not warrant operation. In one case in which a pathological diagnosis was made of hemorrhagic pancreatitis, there was no hemorrhage in the abdominal cavity, but the pancreas itself was involved. This patient gave all the acute symptoms of pancreatitis, and at the autopsy an ulcer of the duodenum was found, which had a direct communication with the head of the pancreas.

Dr. George W. Crile of Cleveland said that in making cultures from the gall-bladder in these cases of chronic infection or chronic pancreatitis, he had seen much better results from the use of autogenous vaccines than from drainage alone, that is, following the use of autogenous vaccine *plus* the drainage. Furthermore, large doses of urotropin for a certain period of time were of value. Again, in cases of acute hemorrhagic pancreatitis he called attention to the value of nitrous oxide anesthesia.

Dr. John C. Munro of Boston stated that the paper of Dr. Guerry reminded him of a case in which he did a cholecystenterostomy six or eight years ago for a lesion at the ampulla, but which proved to be a case of chronic pancreatitis. A diagnosis now could undoubtedly be made both in the chronic and in the acute forms of pancreatitis in a fair number of cases. He had had quite a number of acute cases of pancreatitis and in a fair proportion of them had been able to make an accurate diagnosis before operation. The type of jaundice, both in the acute and chronic forms, was rather significant, although it was not an absolute sign on which to depend. He favored operating upon very acute cases.

Dr. O. H. Elbrecht of St. Louis said he would like to report briefly a case which differed somewhat from those mentioned. It was a case of chronic pancreatitis, the patient coming from an insane asylum, presenting the picture of an acute gallstone attack, with profound icterus. The pain was severe. The case was diagnosed as gallstones, with probably the escape of the gallstone through the intestinal wall. A definite lump could be felt in that region, and they found dense adhesions everywhere, and an immensely distended gall-bladder. The gall-bladder was drained. As the patient was in a bad condition they did not care to explore the region of the pancreas, as it was not suspected at the time. The patient died the next day, and autopsy revealed the case to be one of primary tuberculosis of the pancreas. Sections were made from an ulceration at the tip of the pancreas and found to contain innumerable tubercle bacilli.

Frequency of Cancer.—Dr. Roswell Park of Buffalo said that cancer was one of the most important problems which confronted the medical profession to-day. He believed cancer was on the increase as a disease of modern life. When he began work in this direction there were in New York State fourteen thousand deaths from tuberculosis each year, and about five thousand deaths in cases of cancer. Now the mortality from tuberculosis had been reduced to eleven or twelve thousand cases a year, while the mortality from cancer had risen to nearly eight thousand. Their studies had established the fact that cancer was prevalent in certain localities and in certain houses. They found there were certain places where cancer was more prevalent than in others, and in a considerable number of houses several deaths from cancer had taken place. With regard to heredity, it was now stated as a fact that the disease was not transmitted by inheritance, but there was a possibility of the transmission of predisposition. This was a very important question for the laity and for us. The infectivity of cancer was quite generally established. Last year, at the meeting of the International Congress of Surgeons in Brussels, the question of cancer was discussed for three separate days, and of some three hundred who were present out of a membership of six hundred, he found the majority of surgeons present believed in the infectivity of cancer. There were still some doubters of this theory. The very fact that metastases occur during cancer was the best demonstration of its infectivity, and for him every instance of metastasis in a given case was an expression of a reinfection from the original source. As to the contagiousness of cancer, they had far more proof for its contagiousness than leprosy, or some other diseases that were considered more or less contagious. The early diagnosis of cancer was difficult, and in many instances impossible. Cancer had no definite symptomatology. If cancer could be diagnosed or recognized early, and if it were accessible to their present means of attack, and if it were thoroughly removed it could be cured, but there were "ifs" standing up in tremendous proportion, and they were insuperable apparently.

Suture of the Recurrent Laryngeal Nerve, with Report of a Case.—Dr. J. Shelton Horsley of Richmond, Va., stated that after a thorough search of the literature, he had been unable to find a report of any case in which the recurrent laryngeal nerve was sutured. There had been considerable experimental work done, chiefly by those interested in veterinary surgery, in which the left recurrent laryngeal was divided, and implanted higher up in the vagus. Most of these experiments had resulted successfully, so far as restoring the function of the laryngeal muscles supplied by the left recurrent nerve was concerned. He reported a case in which the left recurrent was injured by a bullet wound. The case was referred to him about three months after the injury. The patient was examined by a laryngologist, and all of the muscles supplied by the left recurrent laryngeal were found completely paralyzed. An incision was made along the anterior border of the sternocleidomastoid muscle and the injured nerve was easily found in the groove between the esophagus and trachea. The diseased portion was excised, except a small filament consisting of the posterior part of the nerve sheath. The ends of the nerve were brought together with a single suture of No. O chromic catgut in a fine-curved needle. Some muscle tissue was drawn over the sutured nerve. The wound healed by first intention and the patient left the hospital nine days after the operation with no improvement in voice or in breathing at this time. The improvement was gradual, however, and two reports from a laryngologist were made

after the operation. The first about two months after the operation showed improvement in the muscles and the second report, fifteen months after the operation, stated the laryngeal nerve had fully recovered. The case was apparently unique.

Treatment of Wounds of the Heart, with Report of Two Cases.—Dr. WALTER C. G. KIRCHNER of St. Louis said there had been five cases of cardiorrhaphy with three recoveries at the St. Louis City Hospital. He reported two of his own cases: one patient died four hours after the operation, and the other made a successful recovery. In the first case there were two wounds of the ventricles, and in the second there was a wound of the heart, one and three-fourths inches in length, which penetrated the left ventricle. The symptoms and treatment of injuries to the heart were outlined. He laid special stress on the method of approach to the heart of these injuries. He considered all wounds of the heart as serious, and gave the following conclusions: "The heart may be manipulated without serious injury to the organ and is amenable to surgical interference. Hemopericardium with heart tamponade is a serious complication and demands prompt drainage of the pericardial sac. In suspected injuries to the heart, the wound in the chest should be carefully explored so that the extent of the injury may be determined, and in cases of doubt, exploratory pericardiotomy is indicated. Small wounds of the heart may heal spontaneously, but in all cases where hemorrhage from the heart exists, the wound should be sutured promptly. In operations upon the heart, when pulsations suddenly cease, massage of the heart and artificial respiration should be tried as aids in resuscitation. With a minimum amount of anesthetic the healthy lung is capable of performing its function, though to a less extent, even when the pleural cavity is exposed. Time is an important factor in injuries to the heart, and an early diagnosis should always be made. The immediate treatment should be directed to the control of hemorrhage and shock. The chief remote complications result from infections of the pericardium and pleura. In treating injuries to the heart, the surgeon should have in mind a definite plan of attack, and the kind of flap to be used in approaching the heart should be determined by the nature of the wound in the chest."

Circumscribed Serous Meningitis of the Cord.—Dr. JOHN C. MUNRO of Boston stated that an interesting paper on this subject by Spiller, that appeared in the *American Journal of the Medical Sciences* for January, 1909, explained a condition which he had observed a number of times at operation and for which he had previously obtained no satisfactory explanation. At the time of his earlier cases (1897) he reported the findings to pathologists, who not only gave him no light on the subject, but even questioned the existence of the lesion. In a small collection of cases of laminectomy reported at the meeting of the American Medical Association in 1904 he called attention to one with syringomyelia and to another diagnosticated as subacute fracture-dislocation, in which he found a "collection of clear fluid under a distinct arachnoid membrane," in which the removal of this fluid produced marked amelioration in the pressure symptoms. This phenomenon and the relief that followed the removal of a soft extradural myeloma here in another case led him to say that there was a something that produced grave paralysis that was demonstrated clinically, which appeared totally inadequate and for which they had no corresponding experimental nor post-mortem explanation. There was no definite cause known for the lesion. Trauma, syphilis, caries, tuberculosis, glioma, influenza, gonorrhea had all been more or less intimately associated with the lesion. In other cases nothing could be found as the primary cause. Whatever the cause, the important thing for them to recognize clinically was the fact that such a condition might exist and that laminectomy was the only rational treatment. In uncomplicated cases the outlook was most encouraging. In complicated cases most distressing suffering could be relieved. Patients always suffered from pain and at times it was intolerable. It might start as a lumbago; it might be girdle-like; it was diffuse and not referred to one nerve root. Paralysis or paresis began generally as weakness of the lower limbs. Spasticity was almost always present and sooner or later there was paraplegia sufficient to render the victim bedridden. Sometimes they found urinary and fecal incontinence; sometimes the upper extremities were more or less affected. Spasmodic contractions, excited by a light touch, were often most distressing. In simple cases the limbs were well nourished, the muscular power was good and there was no trophic disturbance. The reflexes varied among individuals and in the same case. Sometimes they were increased, sometimes absent. Anesthesia might be absolute or very slight. It varied in different regions in the same case and from time to time. So also might the other phenomena of sensation. The onset might be short, a few days after traumatism, and years in other types. Laminectomy by relieving the localized pressure cured the uncomplicated case. Lumbar or local puncture was futile.

Abdominal Cesarean Section for Puerperal Eclampsia.—Dr. LANE MULLALLY of Charleston, S. C., in his paper reported four cases of puerperal eclampsia. The first two patients were brought into the hospital with the usual history of eclampsia, each having had convulsions for about six hours before being admitted. The first case was delivered under anesthesia by dilatation, instrumental and manual and high forceps, and the second by similar dilatation and version, each case occupying from one to two hours. In the first case convulsions continued for twelve hours when the patient died. The second case had several convulsions after delivery and recovered. The third case was a multipara with considerable scar tissue in the cervix; she was anesthetized and an hour or more uselessly spent in attempted dilatation. Finding it impossible to dilate the cervix, he determined upon abdominal cesarean section, preferring this to vaginal cesarean section, and delivered the child in seven minutes. The whole operation when completed occupied twenty-seven minutes. The case was a six-months pregnancy and the child was dead when delivered; in fact, the child was dead before the operation was begun. In the fourth case of full term pregnancy the woman had convulsions every fifteen minutes. In this case he did an abdominal cesarean section at once, delivered the child in six minutes, closed the wound and the patient was returned to the ward in twenty-six minutes from the time operation began.

(To be continued.)

PHILADELPHIA NEUROLOGICAL SOCIETY.

AT the joint meeting with the New York Neurological Society, held December 18, Dr. CHAS. S. POTTE exhibited "A Case of Tic of the Tongue." The patient was a man, who twenty years before, in consequence of some cutaneous irritation near the mouth, began to protrude his tongue in an effort to secure relief. Gradually the habit became established, and at the present time the man in paroxysms of varying duration and recurrence opens the mouth widely and protrudes the tongue to the utmost. These movements are attended with no particular satisfaction or discomfort, and they are induced by no irresistible impulse. Dr. JOHN K. MITCHELL presented "A Case of Amyotrophic Lateral Sclerosis, or Lead-Poisoning." The patient was a house painter who had suffered from symptoms of lead-poisoning on two previous occasions, but who came under observation with fibrillary muscular twitchings, exaggerated reflexes, muscular wasting and weakness, and with bulbar

symptoms, difficulty in speech and in swallowing, and atrophy of the tongue. Dr. D. J. McCarty demonstrated "A Case of Presenting the Symptomatology of Paramyoclonus Multiplex." The patient was a young man with mental deficiency who had presented from birth involuntary, incoordinate movements of the right upper extremity, with some weakness in the right lower extremity and increase in the reflexes. Dr. F. X. Dercum exhibited "A Case of Athetosis and Astereognosis of Sudden Onset." The patient was a man who presented irregular, involuntary, incoordinate movements in the left upper extremity, with deranged sensibility and loss of the sense of recognition of objects by the left hand. The symptoms were thought to be due to a lesion in the neighborhood of the optic thalamus. Dr. Dercum presented also "A Case of Athetosis and Astereognosis of Gradual Onset Associated with Signs of Multiple Lesions." The patient was a woman who exhibited athetoid movements of the right hand, together with various derangements of sensibility in the right upper extremity and on the anterior and posterior aspects of the chest. Drs. Wm. G. Spiller and Chas. H. Frazier presented a communication entitled "The Treatment of Spasticity by Resection of Posterior Spinal Roots," and they exhibited a patient on whom the operation had been performed with relief. The case occurred in a man who exhibited such a marked degree of spasticity of the lower extremities as to be unable to get about. Division of the posterior roots of the second, third, and fifth lumbar nerves was followed by improvement sufficient to permit the man to get about and to go up and down stairs with the aid of crutches. Dr. Chas. H. Frazier presented a communication entitled "Division of the Auditory Nerve for Persistent Vertigo and Tinnitus," and he reported the case of a woman suffering from deafness, with intense vertigo, on whom the operation was performed, but without the desired success. The operation has thus far been performed in only a small number of instances, and the results have scarcely justified the expectations. Some of the patients succumbed directly or indirectly to the operation and others were not relieved of their symptoms. Dr. M. Allen Starr presented photographs of a child of eight years exhibiting unilateral facial atrophy; these pictures were sent to him by a former student practicing in Australia, and he stated that the patient was the youngest within his knowledge in which this disease had been observed. Dr. Chas. K. Mills presented a communication entitled "The Clinical Study of Changes in Sensibility Due to Organic and Functional Diseases, Especially with Reference to Methods of Testing." He considered the various forms of sensibility and the significance of their derangement, and he discussed the methods of testing, describing a number of forms of apparatus devised for this purpose.

A Form of Spasmodic Paralysis Due to Hereditary Syphilis in the Child.—A. B. Marfan describes a spastic paralysis occurring in children which he believes to be due to hereditary syphilis. It occurs from the age of four to seven years, in children whose birth has been normal and who have appeared up to that time perfectly healthy. It comes on insidiously and progresses slowly. There is a paraplegia accompanied by spasm of the muscles of the legs, and partial flexion of the ankles and knees, which causes the feet to be dragged, the toes scraping the ground. This spasm is absent when the child is in repose, but the reflexes are much exaggerated. Argyll-Robertson pupil is present. There is no trouble with sensation nor with the sphincters. Electrical examination shows faradic contractility to be exaggerated, and galvanic reaction normal. The intelligence is affected. The pathological condition indicates a myelitis involving the pyramidal tracts. In such cases the eyes should be carefully examined as to the reaction of the pupils and the presence of a parenchymatous keratitis. The author believes that this peculiar symptom complex is the result of syphilitic changes in the blood vessels and connective tissue of the pyramidal tracts. The result of mercurial treatment is not satisfactory.—*La Presse Médicale.*

A REPORT ON SOME OF THE LARYNGOLOGICAL WORK OF THE BRITISH MEDICAL ASSOCIATION AND OF THE XVI. INTERNATIONAL MEDICAL CONGRESS IN 1909.*

By D. BRYSON DELAVAN, M.D.,
NEW YORK.

IT was my privilege to attend two important meetings last summer, one that of the Section in Laryngology of the British Medical Association, the other that of the corresponding section of the XVI. International Medical Congress. Many topics were brought forward and discussed. All of them were of decided interest. The official program of the Section in Laryngology at Budapest announced 115 papers. The authors of most of these were present, and the papers were read. Several additional papers were offered after the publication of the program. The Section in Laryngology of the British Medical Association was ably presided over by Dr. St. Clair Thomson. The chief presiding officer of the section in laryngology at Budapest was Professor Emerich de Navratil, without question one of the most distinguished of living laryngologists. He was aided by other co-presidents, one of them the well-known Professor Onodi. The spirit of these meetings, actuated by the dignity and geniality of their respective presiding officers, was particularly delightful. At both of them the best of good feeling prevailed and with it every evidence of a strong desire on the part of those who participated to advance the science of the study of diseases of the upper-air passages in the most wholesome and substantial way.

The subjects represented at the International Congress covered a somewhat wide range. Thus, ten papers were upon cancer of the larynx; ten more upon tumors of the nose and pharynx; six upon new methods for the exploration of the upper-air passages; eight upon the treatment of cicatricial stenosis of the larynx; several upon Hay-asthma and several more upon ozena; at least fourteen upon the nasal sinuses; six or more upon scleroma and as many upon tuberculosis of the larynx; ten upon adenoids, and a few upon the tonsils; eleven upon recurrent paralysis and other affections of the nerves of the larynx; seven upon intranasal operations and a number more upon various miscellaneous topics.

I have selected three of these subjects as presenting features of especial interest: (1) The Treatment of Suppurative Diseases of the Nasal Sinuses; (2) Cancer of the Larynx; (3) The Treatment of Cicatricial Stenosis of the Larynx.

*Presented at a meeting of the Laryngological Section of the New York Academy of Medicine, November 24, 1909.

Suppurative Diseases of the Nasal Sinuses.—At Budapest the discussion on the first of these was opened by Dr. M. Hajek of Vienna in a paper entitled "The Treatment of Empyema of the Nasal Sinuses," and by Professor A. Onodi of Budapest in a paper upon the "Intracranial and Cerebral Complications of Diseases of the Nasal Sinuses." A number of other papers were read upon the same general subjects, many of them of distinct value. Several of them dealt with the conservative treatment of sinus disease. The discussions which followed were participated in by the best representatives of the subject in Europe. Among them Professor Killian of Friebourg, Prof. Chiari of Vienna, and Prof. Jansen of Berlin. Prof. E. Fletcher Ingals of Chicago read a masterly paper upon the intranasal treatment of suppurative diseases of the frontal sinuses. The most interesting speaker who took part in the discussion was Professor Hajek, who spoke with rare wisdom and discrimination, giving evidence of full knowledge of all that had been done in this field but appreciating the value of those more difficult but less dangerous methods which, in the hands of a sufficiently skilful operator, are capable of effecting cure without resort to the more radical external operations in common vogue.

The papers of Professors Hajek and Onodi are given *in extenso* in the preliminary transactions of the Section in Laryngology of the XVI. International Congress, a copy of which may now be found in the Library of the Academy of Medicine.

The subjects of the debate and the deductions which may be drawn from it may be stated as follows: Many operators justified their resort to extreme radical measurers in operating upon these cases upon the plea that radical operation is necessary in order to save life. Often this is without doubt true. To say that severe radical measures, however, are always necessary or that life has been in jeopardy in all cases in which they have been applied is to ask too much. No one to-day denies for a moment that there are some cases which absolutely demand radical measures and are clearly beyond the reach of any others at present within our power. All of us have had to deal with such. We are not only willing but glad to recognize the splendid rôle which radical surgery has played in relieving them. Such operations as those devised by Luc, Ogston, and others, not to speak of those of more recent date, have been welcomed by every intelligent specialist who has recognized the needs of the situation and who has found in these operative measures the means of curing cases which before had been entirely beyond control. For these cases radical surgery has been an unquestioned blessing. Where the disease has been of long standing, where the soft parts have been seriously affected, and particularly where necrosis is present, radical operation can hardly be dispensed with. All cases of suppurative

sinus disease, however, are not of this severe type. Some on record have been dealt with successfully by intranasal treatment. This has often been proved in the practice of men of especial skill in this department. In cases of this type the advocates of radical surgery would perhaps determine to operate at once when those skilled in treatment by intranasal methods would at least endeavor to help the patient without surgical operation, and, as experience has abundantly proved, would succeed in doing so in at least a fair proportion of instances.

Where no great injury to the patient would be likely to result from delay it would seem fair that such cases should be allowed the privilege of an effort to secure relief through intranasal means before radical treatment was resorted to, rather than that the radical operation should be done without any attempt at cure by means of the less severe methods.

The third type of case represents a class in which radical operation is in my opinion positively contraindicated; in the hands of the sufficiently skilful operator they can be cured and are cured by intranasal treatment. In these cases radical surgery is out of place. Nevertheless we are not infrequently consulted by patients representing this class to whom radical operation has been strongly advised. The proposition that radical operation is necessary to save life contains two fallacies; the first we have just explained; the second is quite as important as the first. Not a few radical operations have ended fatally and the life of the patient has been directly lost through the operation itself. Possibly, of course, if the operation had not been done, the patient would have died of the disease, but we all know that in cases where operation has been refused, the result has not by any means invariably led to a fatal issue. Hajek called attention to the fact that the proportion of cases of brain abscess complicating sinus disease had been greater since the introduction of radical surgery than it was before.

From a general view of the whole matter extending backward to the time when attention was first directed to these troubles, many things have been learned with regard to the nasal sinuses. Great benefit has been accomplished to those suffering from their diseases. Hand in hand with such men of genius as Bryan in our own country and Zuckerkandl, Greenwald, Onodi and Hajek abroad have been the originators of the radical surgical methods which, variously modified and described under other names, are used by us to-day. These men and the ones who have followed them, of both classes, namely, those skilled in intranasal methods and those who operate from without, have succeeded in greatly alleviating human suffering. Why should there be any question, therefore, as to the relative value of the two general methods? Without question radical methods are not only indicated but are absolutely indispensable in certain cases; equally true is it that in certain other cases intranasal treatment is amply sufficient. The perfection of knowledge at the present time would consist, therefore, in the clear recognition of the conditions present in a given case and accurate judgment as to the best means of relieving them. Giving all praise, and that not a little, where credit is due, it nevertheless appeals to me as unfortunate that this matter, in common with so many other surgical questions of a like nature, should not be placed upon a firm scientific basis. Obviously the only way in which this can be done is through the careful observation of the cases through long periods of time after the date of the operation and through the truthful reporting of all cases, good and bad alike. At the meeting at Budapest it was impossible to learn from many of the leading speakers just what their results had been.

Cancer of the Larynx.—The subject of Cancer of the Larynx came up both at Belfast and at Budapest. At Belfast Dr. R. H. Woods of Dublin presented a remarkably successful case of extirpation of the larynx. The chief interest attaching to this, however, lay in the presentation of a new vocalizing apparatus in the use of which this patient had been instructed. In describing the apparatus of Dr. Woods it should be said that it differs from the one devised by Prof. Gluck of Berlin in that with the latter the tube is carried from the trachea and when held in front of the patient's mouth it reinforces the resonance of that cavity, especially for vowel sounds, in such a way that by listening carefully one is often able to understand what the patient is attempting to say. Dr. Woods has carried this tube a little further, put a reed into its distal end, and introduced the reed into the pharynx through the nose. In this way the patient by blowing through the tube actuates the reed in his pharynx and the sounds thus produced take the place of those ordinarily made by the vocal cords, with the result that the patient is able to speak as well as before operation except that he speaks in a monotone. This, however, is a small objection when the perfection of the result in every other respect is considered. The effect produced by the apparatus of Dr. Woods is that of a wonderful reproduction of the normal tone of the human voice. Nothing just like it has ever been presented before. It is devoid of the objections commonly met with in such forms of apparatus as are made of metal and designed to wear in the laryngeal space. These have been invariably irritating to the surrounding parts. The note produced by them has been so unnatural as to make the employment of the apparatus next to impracticable. By using reeds of different sizes almost any quality of tone can be afforded by Dr. Woods' apparatus so that the different qualities of voice can readily be simulated. In the opinion of the writer this apparatus is the best device of its kind that has ever been presented.

The work of the section in laryngology at Budapest was opened by an excellent paper by Sir Felix Semon upon the subject of Simulated Cancer of the Larynx. In this the various diagnostic signs of carcinoma of the larynx were alluded to and a series of cases presented in order to illustrate the difficulties which sometimes exist in arriving at exact conclusions as to the nature of a given intralaryngeal growth. In such cases mistakes of diagnosis are not uncommon. The paper reported 13 cases. Of these three showed appearances very similar to one another, all resembling cancer, and yet were due to absolutely different causes and non-malignant. The first was a chronic infective inflammation, the second an extravasation of blood into the right vocal cord, and the third tuberculosis. Three or four other cases illustrated the difficulties sometimes met with in the differential diagnosis between tuberculosis and malignant disease of the larynx. A brief history of each case is given and each is accompanied by an admirable illustration, accurately representing the picture seen on laryngoscopic examination. This contribution is based upon an experience gained by the study of 246 cases of malignant disease of the larynx. In closing the author says: "I trust that by frankly reporting the various difficulties and errors

that have occurred in my own practice I have not nursed in the hearts of any the feeling that the diagnosis of malignant disease of the larynx is a desperately difficult matter. No doubt sometimes it is, but after all I have observed only 13 cases in which real and serious diagnostic difficulties existed. Thirteen out of a total of 246 observations will suggest that the percentage of exceptional difficulties is only a small one. As a general rule, the diagnostic signs at our disposal are trustworthy." In the experience of the writer the diagnosis of cancer of the larynx is not always easy. There are some cases which present difficulties apparently only to be overcome by careful microscopic examination of the whole substance of the growth, while in other cases a growth which may be recognized as malignant after careful study and observation will be impossible of recognition as the result of a single examination of the larynx. In the diagnosis of these cases, therefore, it is not to be expected that one consultation will in every case offer opportunities which will enable a positive diagnosis to be made. This is particularly true when tuberculosis and syphilis are to be excluded through careful examination for the one and a tentative course of specific treatment for the other. While close observation of the growth by one of skill and experience will generally reveal its true nature there are not a few cases in which visual examination alone is insufficient for a positive diagnosis. The article of Semon is suggestive and interesting. The illustrations which accompany it are enlightening and are deserving of careful study.

Of the other contributions to this subject at Budapest by far the most interesting was the paper of Prof. Gluck of Berlin upon the diagnosis and treatment of carcinoma of the larynx and, especially, the presentation by him of four cases upon which he had performed his most extensive operations for the removal of widespread disease of the throat, including a total extirpation of the larynx and the removal of affected adjacent parts of the esophagus, pharynx, tongue, and the lymph nodes. All of these patients had survived for a period of two years and all appeared to be in fair condition. The mutilation caused by operation, however, was so extensive that it seemed incredible that life could be sustained; much more difficult to believe that the patient's existence could be endurable. In each case the whole front of the throat seemed to have been obliterated and practically speaking much if not everything, from the neighborhood of the base of the tongue to the episternal notch removed as far back as the vertebræ. This may be an exaggeration, but the result was a vacant space of surprising extent. The cases presented by Prof. Gluck were interesting from at least two points of view. First, as proving the possibility of such extensive resections of important parts of the throat, and secondly, the possibility of prolonging the lives of patients in whom carcinoma has extended so far outside of the larynx as to make a simple laryngectomy useless. To such cases which in the hands of many surgeons would be considered beyond relief, the operations of Prof. Gluck offer a ray of hope. Unfortunately, however, it must be stated that it was not explained in how many cases the patients had succumbed early to the effects of operation. Until we are better informed as to the mortality rate we are unable to judge of the actual value of this work.

With regard to cancer of the larynx and its treatment to-day it may be said that comparatively little new information has been offered for many years. Operations are being constantly performed upon the larynx, however, and two propositions have been placed beyond contradiction. First, that such work improperly done can only lead to disappointment and failure, and second, that, of the operative work now being carried on in this country and abroad there is none on the whole as successful as that which has been inspired by the able leadership and instruction of Mr. Henry T. Butlin. To him more than to any one man belongs the credit of having evolved a system of treatment by which the largest number of cases can be benefited and the greatest prospective period of time added to the existence of the patient. Early operation, skillfully performed under rules long since laid down by Mr. Butlin after careful study and experience on his own part, has without question gained its place in surgery. Until some better procedure has been provided it must be regarded as by far the most promising method. This has been recognized in England by an ever-increasing number of practitioners, with results which seem to justify these statements. I have long since insisted that in so far as these views are respected and followed out the treatment of laryngeal cancer will meet with the maximum of success. On the other hand, in so far as they are neglected, failure and disappointment will result. Long observation has proved the truth of this statement. I can only reiterate it with increased emphasis founded on constantly accumulating experience. Success in important operations upon the larynx can only be gained through the same principles of action as made possible the discovery of the North Pole. The novice, the careless or unprepared operator, the man who does his work in an institution supplied with inexperienced internes and nurses ignorant of this particular class of work will never succeed. Many years ago I expressed my views upon this subject, and in no uncertain language. Fortunately, a few men among us have at last acted upon them, with results which already go far to prove their value.

Treatment of Cicatricial Stenosis of the Larynx.—This subject was invested with peculiar interest on account of the recently suggested method known as "laryngostomy." It was discussed at both meetings. At Belfast the discussion was opened by Dr. Lambert Lack of London, Dr. Delsaux of Brussels, and Dr. Delavan of New York, and was participated in by Dr. Emil Mayer of New York, and Dr. Logan Turner of Edinburgh. The paper of Dr. Lack dealt chiefly with the subject of stenosis of the larynx in children as the result of diphtheria. He offered nothing particularly new. Various methods of treatment were referred to by him and condemned. Dr. Lack's experience with intubation in these cases had also been unfavorable and this method was condemned by him. It is interesting to know, however, that he had based his opinion on the subject of intubation in chronic stenosis upon the study of but two cases, that he had employed the method upon these cases for but two or three weeks, and at the end of that time had decided that the method was a failure, because the patients were not cured. We do not know with how much skill or otherwise the intubation was managed. The time of its employment, however, a few weeks, was entirely insufficient, as has been explained by all experienced in its use.

The paper of Dr. Delsaux was a description of the new method of Gluck, known as laryngostomy and recently presented to the medical world by Saignon

and Barlatier. In it a careful résumé is given of the study of 37 collected cases operated upon by various surgeons. Unfortunately, of the 37 patients treated, six died, a mortality of 16 6/10. Starting with this knowledge, we have some basis upon which to estimate the relative value and the relative risk of this method. For this the scientific world owes Dr. Delsaux a debt of gratitude. Of the remaining 31 of Dr. Delsaux's 37 cases, there were 14 in whom the final plastic operation had been completed. These were considered entirely cured and up to the present time had in no case suffered recurrent stenosis. Of the remaining 17 cases the process of dilatation in 14 was still going on and the plastic operation for the closing of the opening in the neck had not yet been performed. Three cases had disappeared and one case failed. Usually, the patients operated upon in this way were able to make themselves understood in conversation, and some had even recovered their voices, owing to alleged reformation of the vocal bands. Dr. Delsaux concluded from these statistics that laryngotracheotomy had proved the most successful method for the cure of these cases, that it was the operation to be preferred in the treatment of them, that it was an operation attended with little risk, and that it should become the routine method of dealing with cicatricial stenosis of the upper-air passages.

In a paper of Dr. Delavan three things were stated as essential to the successful management of stricture of the larynx: (1) that the stricture be relieved; (2) that the relief be permanent, and (3) that the treatment be conducted with the least possible injury to the parts involved. The last proposition was particularly insisted upon. The writer laid all possible stress upon the necessity for so conducting the case that the least injury possible be inflicted either within the larynx or from without. He regarded this as one of the most important considerations which could affect the subject under discussion and believed that before the acceptance of the new methods which involved so much of operative work outside of the larynx clear proof should be adduced to show that these extensive operations were not in the end productive of harm. Very often operative measures had aggravated the stenosis rather than relieved it. He called attention to the proposition that success in cases treated by intubation depends upon the constant and long-continued distention of the stricture, on the principle that scar tissue in general, when subjected to continuous stretching, will in time lose its resiliency. Illustrations of this loss of resiliency in scar tissue are found in various other departments of surgery, for instance in the stretching of abdominal scars after laparotomy or after operation for hernia. For the indications present in cicatricial stenosis the O'Dwyer tube answers every purpose and the larynx tolerates its presence indefinitely. Much clinical evidence had been accumulated in this country to prove the value of the O'Dwyer method. Relief by any form of operation could only be proved to be permanent by the lapse of years without recurrence. Injury to the parts, either through endolaryngeal or extralaryngeal operation was by no means a negligible factor, and as far as possible must certainly be avoided. Attention was also called to the possibilities of the development of laryngeal disease, possibly remote, subsequent to the time that operative work upon the larynx had been carried on and the necessity was pointed out for a careful observation of such cases long after treatment.

At Budapest the discussion of this subject was opened by Prof. Ucherman of Christiania, Norway, who condemned intubation, because in cases of diphtheria and the like the internes in his hospital had been unable to manage their cases with success.

It thus appears that two of the main objections against intubation in Europe have been based, first, upon insufficient knowledge of its use and its application for too short a period to be productive of benefit and, secondly, through the handing over of the method to inexperienced beginners, who could not for a moment be supposed to possess the skill necessary for its proper management.

At Belfast Dr. Emil Mayer made a strong plea for the O'Dwyer method, illustrating his remarks by reference to his own series of cases successfully treated in this way and explaining its superior advantages.

At Budapest the writer strove to impress the fact that intubation is an art, that the practice of any art worthy of the name could never be assumed in a desultory manner by those ignorant of its principles and that it was therefore no argument against intubation to say that those untrained in its use had failed in its successful application. He also called attention to the importance of the method, a method which for years had been applied with great success in all parts of the United States. Such men as O'Dwyer, Rogers, and others had done their part toward exploiting it, and it remained for the rest of the world to appreciate its value and to test with proper care and skill what had been presented. The open method, namely, that known as laryngostomy, had been so recently suggested that it was quite too early to predict its ultimate value. While any method would be heartily welcomed which would produce the desired result with the least amount of trouble to the physician and distress to the patient, it was still necessary to convince us by practical demonstration that a better method had yet been brought forward than that of O'Dwyer.

In the discussion which followed it was suggested that the care of patients, especially children, after laryngostomy was both difficult and painful and that the frequent dressings required, involving the frequent withdrawal and reintroduction of the tubes, was attended with much distress. This was not denied by those who had had experience in the matter. In the case of intubation the tube in many cases may be retained for long periods of time and even its reintroduction is not necessarily as distressing to the patient as is the ordinary dressing after largyngostomy.

In considering the sum total of the work presented at these meetings we are struck with the fact that there is little novelty in it. Indeed, the more one considers the work of the present time the more he is impressed with the importance of going backward and studying carefully the methods of the great masters of laryngology who flourished a quarter of a century ago. Many valuable lessons are to be learned, among them this, namely, that not all of the good things of laryngology are utilized by us to-day. In certain instances methods which were recognized as valuable a number of years ago have been completely supplanted by others not nearly as good. It must also be remembered that a new thing is not necessarily better simply because of its novelty. Another thing which is somewhat distressing is the ease with which the names of our instructors have in so many instances been forgotten, simply because

some recent successor has made a slight modification in a method which in itself is classic. I am inclined to think that a little too much credit is being given at the present time to certain operators upon the nasal sinuses at the expense of those to whom we are really indebted for our best knowledge of the subject. Thus, a name may have swept all others out of sight, whereas without the suggestions of those who prepared the way the present methods of operating would probably not now be in existence. Moreover, and much more important than all of this, there has been a tendency of late years to forget, or to underestimate the value of intranasal treatment for the relief of these conditions. Many a case in the experience of the writer has been subjected to radical operation, which, in the hands of a really skillful master of this department, would have been cured by intranasal means. The names of Bryan and others of his way of thinking are no less illustrious throughout the world to-day than they were before radical operations upon the sinuses became so common. Nor are his methods and those of the men who have followed him any less desirable than before. I believe that too little attention has of late been given to this department of the work. First, because radical operation is attractive and savors more of novelty, and, secondly, because, all things considered, it must be admitted that in many instances the external radical operation is actually easier of performance than is treatment by the other means.

After all, here, as in all other departments of surgery, wide and accurate knowledge, based upon rich experience, keen judgment, and finally, a highly conscientious view of the best interests of the patient are essential. Another thing which has impressed me is the rarity with which even the best operators are willing to truthfully report their unsuccessful cases. A shining exception to this was the statement of Delsaux in his treatment of the subject of laryngostomy, in which, as I have already said, he fearlessly reported a mortality of 16.6 per cent. Few of those who have written upon the subject of laryngeal cancer have made it possible for us to derive any idea whatever as to the actual mortality reached in these operations; while in the department of suppurative diseases of the sinuses some of the leading men in Europe refuse to state their final results.

The symposium upon sinus diseases at Budapest gave evidence of a strong tendency toward a more careful and conservative consideration of radical methods. Its result will be to recall the attention of the profession to the possibilities of intranasal treatment.

THE IMPORTANCE OF CORRECT DIAGNOSIS OF DISEASES OF THE EYE.*

By A. EDWARD DAVIS, M.D.,

NEW YORK.

PROFESSOR OF DISEASES OF THE EYE, NEW YORK POST-GRADUATE MEDICAL SCHOOL AND HOSPITAL.

Some months ago, to be exact, February, 1908, it was my pleasure to write a short paper on a subject similar to the one I present to you this evening, to wit, the importance of correct diagnosis in diseases of the eye, being the chief reason why opticians should not fit glasses. That paper was for the purpose, if possible, of preventing the opticians and optometrists from practising medicine, which, I am sad to say, to the shame of medicine in the great State of New York, they have succeeded in doing, thanks to the "wisdom" of an all-wise Legislature and the approval of a Governor, whose judgment, usually sound, seems, in this instance at least, to have been warped by a high degree of astigmatism.

*Read before the Section of Ophthalmology, Kings County Medical Society, Brooklyn, October, 1909.

In the opening paragraph of the paper referred to I stated that "In no branch of medicine is a correct diagnosis of more importance than in diseases of the eye. Not only is this statement true as regards errors of refraction, and local diseases directly affecting the eyes, but indirectly as bearing upon many grave general diseases, as Bright's disease, arteriosclerosis, diabetes, etc., which latter diseases are often first manifested by some disorder within the eyes. In such cases a correct and early diagnosis of the conditions in the eye and a recognition of their significance as an index of some grave disease, together with the institution of prompt and energetic treatment, all are of paramount importance, if we wish to save the sight of the eyes or the life of the patient." And, gentlemen, we who have had a thorough training, both in general medicine and in our specialty, know how difficult it is at times to arrive at a correct diagnosis, even with all our training. And we know full well, and laymen of average intelligence also know, or ought to know, that no one who is not well trained in medicine is competent to understand the relation which nephritis, arteriosclerosis, syphilis, diabetes, and other diseases bear to disorders of the vision. Important as are the relation of the above-mentioned diseases to disorders of vision, I shall not stop to consider them in my brief paper this evening, for we are all familiar with the eye conditions in these diseases, only the atypical cases giving us any considerable trouble to arrive at a correct diagnosis.

It is to another phase of the subject that I want to invite your attention at this time, to wit, the correct diagnosis of the eye conditions in (1) autointoxications, (2) accessory sinus diseases, and (3) tuberculous affections.

Autointoxications.—In discussing the matter of autointoxication it is altogether important to make a clear distinction between autointoxication and autoinfection. As Chapman states, "Specific infectious diseases must not be included with autointoxications; only substances which originate in, or are elaborated within the system should be regarded as causing autointoxications. Thus, mussel or sausage poisoning is a different process from intestinal putrefaction in which poisonous diamins are formed within the bowel lumen. In other words, autointoxication must not be confounded with autoinfection."

Relative to the general organism and autointoxication and relative to the eye also, for that matter, we know but little. In fact, as Alonzo Taylor says, "We do not know the entity of a single autointoxication except the acidosis of diabetic coma."[1]

It is with especial reference to certain diseases of the eye supposed to be produced by autointoxication as the result of intestinal fermentation and the resulting products of enterogenous decomposition that I wish to direct your attention for a moment.

That intestinal toxemia may be considered a contributing etiological factor in the following ocular affections seems likely from the various clinical observations thus far reported. In certain cases of relapsing iritis, chronic iridocyclitis; certain forms of

scleritis and episcleritis and recurring ulcers at the sclerocorneal margin; retrobulbar neuritis; paresis of accommodation, and as intensifying and adding to the toxic agencies in the commoner toxic amplyopias, tobacco, alcohol, etc., by entering into the formation of new and even more violent toxins. For example, in some forms of chronic iridocyclitis and relapsing iritis, no treatment is of much, in fact, of any, aid, unless strict regulation of the diet is carried out together with the use of intestinal antiseptics, tonics, etc.

De Schweinitz and C. A. Fyfe, in June, 1908, at the Section of Ophthalmology of the American Medical Association, presented a paper in which they reported a number of cases of autointoxication in relation to the eyes, in which they had made extensive and exhaustive laboratory examinations of the gastric contents, together with a thorough and complete examination of the urine and feces. They state that while they had not found a single disease of the eyes which of itself would justify the inference that it was caused by intestinal autointoxication; and also that while laboratory examinations revealed no definite toxins to which a single eye disease might be attributed, yet it was worth while they thought to make such investigations as they presented. By such investigations the presence or absence of intestinal putrefaction is established at least, and the nature of the patient's nitrogen metabolism is found out; and it is only by such scientific investigations that we may expect to arrive at the correct diagnosis in these obscure cases, and by instituting a proper régime of diet and treatment expect to give relief, as they have done in some of their cases. De Schweinitz and Fyfe considered an increase in the amount of the conjugated sulphates in the urine as the most reliable test in intestinal putrefaction. The presence of indican in the urine is highly indicative of putrefactive intestinal indigestion. Dr. William H. Porter of this city considers the presence of an excess of indican in the urine as a positive indication of intestinal indigestion and putrefaction, and the test for indican, as above stated, is easily made, even by the busy practitioner. While indican itself is not dangerous it is a danger signal of putrefaction taking place in the intestines. Porter, speaking on this point in regard to toxins and indicanuria states the following: "Taking up the alcohol and nicotine toxemias, it has seemed to me that the result has not been so directly due to the alcohol or the nicotine as to the disturbance produced in the digestive functions by the arrest of the digestive secretions, following which the bacteria of putrefaction have an opportunity to attack the proteids and ultimately give rise to the presence of indican in the urine. The putrefactive bacteria seem to break up the proteid molecule, forming indol and sulphurous acid, and that acid being active combines quickly with the potash salt and forms indoxyl potassium sulphate, which is inert. It is rapidly absorbed from the intestinal tract, carried through the system to the kidneys, and yields indican in the urine. The indican is simply a danger signal indicating that we have the putrefactive fermentation of the proteid molecule. Where indol is formed as a by-product of the full proteid molecule is produced, and that by-product breaks up into numerous forms of toxins, some of which are intensely poisonous. In this way is produced the condition which sometimes irritates one part of the nervous system and sometimes another, and thus we have a logical cause for the multiplicity of symptoms. It is by one of these by-products acting upon the optic centers in the brain that sudden blindness without retinal or nerve lesion is explained."

It is not necessary to go further into details as to the nature of these toxins, as the time and extent of this paper will not allow of the same. An interesting clinical observation made in this connection is that by Dr. Fernandez of Havana, Cuba, in a recent address, October 5, 1909, delivered before the Society of Ophthalmology and Oto-Laryngology, where he states that during the late Spanish-American War, and at its close "We began to note the ocular disturbances produced by alcohol that we had almost forgotten. At the end of this abominable period, partly from the reconcentration of the country people, mostly Cubans, there was noticed another kind of amblyopia, and atrophy of the optic disc, which, although we first thought to be caused by alcohol was due to autointoxication, due to inanition or a very defective or insufficient feeding, induced by the poverty to which the country people were rapidly reduced." This clinical observation only goes to emphasize the fact that we should be on the lookout for such complications with suitable surroundings for producing autointoxication, and this astute observer was quick enough to make this observation.

I shall report but one case here, and that briefly, by way of illustration of autointoxication.

A. M., aged 14, male. Has one brother, younger, and one sister, older; good health. Father and mother living and in good health, although the mother at one time had goiter, of which she has been completely relieved. Syphilis, rheumatism, tuberculosis can be definitely excluded. The patient first consulted me in November, 1900, for slight hyperopic astigmatism and a mild conjunctivitis. With treatment of the conjunctivitis the symptoms were entirely relieved, which consisted of slight asthenopia and itching of the eyes. In February, 1901, the patient had a mild attack of acute catarrhal otitis media in the left ear which was entirely relieved by hot douches and leeches. In April, 1901, his tonsils and adenoids were removed. In 1902 he had his appendix successfully removed. In June, 1908, he again consulted me, complaining of headaches, puffiness of the eyelids, and inability to use the eyes for close work, this condition having prevailed for about six months before having consulted me. Thorough examination of the eyes with correction of the refractive error was made. The glasses relieved his condition only partially. Examination of the urine at this time revealed a very excessive amount of indican, together with a few small hyaline and rarely a finely granular and epitheliated cast, with a strong trace of albumin (see chart, June 26, below). The patient was placed on tonics, nitromuriatic acid, nux vomica, lactated elixir of pepsin, together with remedies, calomel, etc., to clear the bowels. Diet was also instituted to control the condition. He improved but slowly, although kept on this treatment for about two months. Examination of the urine on July 20 showed still an excessive amount of indican and a few casts in the urine, together with a trace of albumin (see chart, July 20, below). By the middle of August the patient's condition had improved markedly. The puffiness of the eyelids had been reduced, the patient was able to use the eyes with some comfort, and the urine showed only a trace of indican and

only a very minute trace of albumin (see chart, August 17, below). Within another month, however, he again had a relapse to the former condition although he had been kept on a pretty rigid diet and under treatment. September 30, examination of the urine showed a very excessive amount of indican with a few hyaline and finely granular casts and a low per cent. of urea. At this time I placed him under the care of Dr. Wm. H. Porter of this city, who went very carefully into the examination of the urine, as I had done myself, which at that time, as just stated, showed a very excessive amount of indican. The patient was placed on a general mixed diet, and was given ox-gall and pancreatic extracts, and as a tonic caffeine and strychnine, also iron. After about eight weeks' treatment he was considerably improved and at the end of about three months albumin and casts disappeared from the urine, asthenopic symptoms were relieved, also the puffiness of the eyelids, and the patient was able to use the eyes with comfort. He is still kept under the observation of Dr. Porter and myself, so far with no relapse.

In this case the eye symptoms were no doubt the result of an autointoxication, but of what autointoxication we are not positive. The important factor in the treatment of his case, as in all such cases of autointoxication, is a thorough examination of the urine, stomach contents, and with the proper treatment to relieve the conditions present, both as regards diet and medicine. No two of these cases of autointoxication are alike and each one has to be studied individually. I thoroughly agree with Dr. de Schweinitz that, although we do not know the nature of these toxines or poisons, it is worth while to make a complete study of the cases if we hope to arrive at the solution of the question.

Examination of urine, June 22, 1908: Spec. grav., 1,020; reaction, acid; odor, strongly aromatic; transparency, clear; consistence, normal; color, dark yellow; appearance of sediment, nebulous, white, very faint.

Chemical analysis: Albumin, negative; reaction with Heller's test, strong trace; sugar, negative; reaction with Fehling's test, negative; bile, negative; urea, 2.2 per cent. (10.55 grs. to oz.); chlorides, normal; phosphates, earthy, normal; indican, enormous excess.

Microscopical Examination: Casts, occasional large and small hyaline, rarely a finely granular, epitheliated, and mixed (granula, epithelia, and blood); numerous mucous shreds; blood, occasional isolated cells; epithelium, occasional vesical and large squamous; pus, occasional isolated leucocytes; crystals, none observed; amorphous deposits, negative. Remarks: Very intense intestinal fermentation (autointoxication); mild (toxic) parenchymatous irritation therefrom.

July 20, 1908: Spec. grav., 1,010; reaction, acid; odor, faintly aromatic; transparency, clear; consistence, normal; color, pale yellow; appearance of sediment, nebulous, white, very faint.

Chemical analysis: Albumin, negative; reaction with Heller's test, trace; sugar, negative; reaction with Fehling's test, negative; bile, negative; urea, 1.5 per cent. (7.2 grs. to oz.); chlorides, normal; phosphates, normal; indican, very excessive.

Microscopical examination: Casts, rarely a small hyaline, finely granular; numerous mucous shreds; blood, none observed; pus, occasional isolated leucocytes; epithelium, occasional large squamous and vesical; crystals, none observed; amorphous deposit, negative. Remarks: Very marked intestinal fermentation (toxic parenchymatous irritation therefrom).

August 17, 1908: Color, amber; sediment, small, flocculent, gray; reaction, acid; specific grav., 1; albumin, very minute trace; sugar, none; urea, 11.00 grams per liter; indican, very minute trace; bile pigment, none; acetone, none; casts, an occasional hyaline, small and large granular; blood, none; pus, some leucocytes; epithelium, few squamous.

September 30, 1908: Spec. grav., 1.010; reaction, acid; odor, faintly aromatic; transparency, clear; consistence, normal; appearance of sediment, nebulous, very faint; color, yellow.

Chemical Analysis Albumin, Heller's test, negative; Esbach's test, trace; chlorides, normal; phosphates, normal; bile, negative. Sugar: Fehling's test, negative; Nylander's test, negative; urea, 1.3 per cent. (6.24 gr. to oz.); indican, very excessive.

Microscopical Examination: Casts, rarely a small hyaline and finely granular; blood, none observed; pus, occasional isolated leucocytes; epithelium, occasional vesical and large squamous; crystals, none observed; amorphous deposit, negative. Remarks: Urea percentage and spec. grav. low; marked intestinal fermentation; otherwise, practically normal.

Accessory Sinus Diseases.—The importance of correct diagnosis in accessory sinus diseases and the presence of such diseases as a possible or probable cause of obscure eye affections, has been given but scant attention, until recent years. That sinus diseases sometimes caused orbital cellulitis and abscesses was recognized, of course, especially if the sinus abscess had perforated into the orbital cavity. Cancerous affections originating in the sinuses and affecting the eyes were also recognized; but that accessory sinus diseases should or could cause optic neuritis, optic atrophy, post-bulbar neuritis, retinitis, choroiditis and general uveitis, to say nothing of the symptoms of amblyopia and asthenopia, frequently present in such cases, apparently did not occur to ophthalmologists and rhinologists. Or, if such an etiological connection was suggested, it was dismissed as too remote a cause. The demand for a more correct and definite diagnosis in these obscure cases of ocular disease stimulated both oculists and rhinologists to a closer study of the anatomical and physiological relations of the sinuses to the orbit and the orbital contents and the optic nerve entrance. Not only were the healthy specimens studied but the pathological and clinical cases, with the result of establishing a direct etiological connection between sinus diseases and many grave ocular affections, such as optic neuritis, retinitis, etc., either by direct contiguity, by pressure, or through the blood and lymph channels; and at times perhaps through toxemia. This relation between sinus diseases and affections of the eye is now so well established and so many cases have been reported that it is not necessary to report others of the graver affections, such as optic neuritis, retinitis, etc., as secondary to sinus diseases; because we are all now on the lookout for such cases. However, I wish to call your attention to some of the minor affections of the eyes which may be secondary to the accessory sinus diseases, lest we forget to consider this factor in such cases. I refer to cases of troublesome asthenopia, unrelieved by the usual methods of treatment with glasses, tonics, rest, etc., or even after a course of rest to the ciliary muscles under the influence of atropine, as practised by some.

By way of illustration I shall report very briefly two cases to the point, recently under my care.

Case I.—June 24, 1909, W. M. S., broker, aged 43, consulted me because of a troublesome asthenopia which glasses had failed to relieve. He complained chiefly of pains in the eyes, more marked in the left, after any reading or close work, also of frontal headaches and general irritability. The patient is a nervous man and prematurely old. Examination of the eyes revealed a mixed astigmatism of high degree, but with correcting glasses vision was brought up to 20/10 in each eye. Even with this acute vision he did not get the desired relief from the asthenopic symptoms, pain over the left eye particularly annoying him. Two months before coming under my care he had a piece of cartilage removed from the right side of his nose. On examination of the right side of the nose it was found free, but on the left side the middle turbinate was swollen and pressed rather firmly against the nasal septum. The patient was just starting for his vacation and so did not have anything done to the left side of the nose. On September 7 he returned to the city and still complained of pain over the left eye and inability to use the eyes. Nasal treatment was now begun, and by relieving the pressure caused by the left middle turbinate bone the pain over the left eye was completely relieved and the patient was able to use the eyes with entire comfort for the first time in many months, and this happy condition still prevails.

Case II.—Miss M. M., aged 34, consulted me for glasses because of severe frontal headaches, especially over the left eye. She also complained of marked dizziness and vertigo, so pronounced at times that she had to catch things to stand. The patient gave a history of a discharge from the nose and dropping into the throat. She stated that she had had her nose treated for two years in one of the clinics in the city in a perfunctory way and without relief. Examination of the eyes revealed no refractive error or pathological condition, and the vision was perfect in each eye. Careful examination of the patient's nose, by Dr. George E. Davis, now revealed a polyp about the size of a hazel-nut, on the left side, high up, attached to the cribriform plate. It made considerable pressure on the frontal part of the upper and middle turbinate bones. This polyp was snared off under cocaine anesthesia with immediate and complete relief of the pain over the left eye, and of the very troublesome vertigo of which she had complained. The patient was discharged, cured, after two weeks' treatment.

These cases show the necessity of complete and thorough examination, not only of the eyes, but of the nose and accessory sinuses in all obscure cases, if a correct diagnosis is to be arrived at.

Tuberculous Affections of the Eye.—Within the last two and one-half years a valuable aid to a correct diagnosis of tuberculous affections of the eye, and for that matter of the general system, has been given to the profession by Wolff-Eisner[2] and Calmette,[3] Wolff-Eisner originating the method and Calmette making many clinical demonstrations of its usefulness. The method, or test, is generally known as the Calmette reaction test. Since their earliest publications in 1907, the method has been tried by many different observers and the literature is rich in reports of cases. That the "ophthalmoreaction" test (Calmette) to tuberculin is a valuable aid in the diagnosis of certain eye diseases, such as scleritis, episcleritis, chronic iridocyclitis and iritis, choroiditis, interstitial keratitis, and phlyctenular keratitis and conjunctivitis, has been fully demonstrated; however, the application of the test to the eyes, especially if diseased, or have been diseased, and at times in perfectly healthy eyes, is not without danger, as serious damage to the eyes has been reported in numerous cases where the test has been used. Eyes that have been inflamed and quieted down have been incited to new inflammation, and, as above stated, even perfectly healthy eyes have been injured. Fortunately we have other tuberculin tests than the Calmette opthalmoreaction, *e.g.* von Pirquet's cutaneous-reaction test and the subcutaneous-reaction test. The subcutaneous-reaction test, by the way, is sometimes used after the other tests to confirm the presence of active tuberculosis, but Zimmermann[4] gives us warning that the subcutaneous test should not be used after the opthalmoreaction test has been made, as it is apt to reproduce the local reaction on the eye or induce it, if it did not occur before with the opthalmoreaction test. The subcutaneous test, however, can be used with perfect safety after the von Pirquet test.

As to the reliability of the opthalmoreaction test as a diagnostic measure, and as to its dangerous effect on the eye itself, opinion is somewhat divided. In a paper read before the Section of Ophthalmology of the American Medical Association, in June, 1908, Dr. Harry C. Parker, Indianapolis, after a careful review of the literature up to that date, and from his own experience with the test, draws among other conclusions the following:

1. The Calmette ocular tuberculin test is of as great diagnostic importance as any other single test.

2. The test is uncertain in patients under two years of age, in whom the cutaneous test of von Pirquet is most certain.

3. Recent investigations have shown a greater number of ophthalmic affections due to tuberculosis than formerly supposed, and in the Calmette reaction we have a simple means of differential diagnosis which should be thoroughly tried.

4. The ocular reaction is especially valuable for ascertaining the tuberculous nature of cases of phlyctenular keratitis and conjunctivitis, episcleritis and scleritis, chronic iritis and iridocyclitis, interstitial keratitis, and choroiditis.

5. A one per cent. solution of Koch's "old" tuberculin is nearly as good as the Calmette solution for diagnostic purposes.

6. The initial instillation should be preferably under one per cent. strength, in order that severe inflammatory conditions may not follow its use.

7. The consensus of opinion seems to be against using the test in an eye not wholly normal.

In a quite recent paper on the same subject, Charles Zimmermann (*loc. cit.*) of Milwaukee, after reviewing the literature of the subject up to date, October, 1909, is not so favorably impressed with the Calmette test. He states that "ophthalmoreaction as to clinical value compared with other local reactions, cannot be considered as absolutely reliable, and its employment requires certain conditions. For instance, more than 1,000 observations have been made by Calmette and his pupils which tend to show that the reaction may be demonstrated in all forms of tuberculosis, unless the patient be moribund or nearly so." Zimmermann also cites Baldwin's experience in 1,087 conjunc-

tival tests, as follows: "It is noteworthy that fully 70 per cent. of persons who had been healed in the clinical sense from two to thirty years reacted positively. The chief interest relates to the clinically incipient (71.4 per cent. positive) and suspected cases (33.3 per cent. positive), in which the test would be expected to assist in diagnosis. The results fall considerably short of the requirements for an ideal diagnostic method in suspected tuberculosis, though relatively good in confirmation of the clinically tuberculous cases."

The experience of other authorities is also cited to similar effect with the ophthalmoreaction test, the consensus of opinion being that a *positive reaction* is indicative usually of active tuberculosis somewhere in the body; but that a *negative reaction* does not exclude tuberculosis, as it often fails to react in very advanced cases of tuberculosis, and also in very young children. W. Stock's experimental investigations are quoted also to the effect that "positive reaction in disseminated choroiditis, iritis, scleritis, parenchymatous keratitis, which clinically and anatomically have nothing characteristic, but may be produced by tuberculosis, does not indicate with certainty their tuberculous nature, as they may be of different etiology (syphilis, or the introduction of fermentation fungi into the circulation). The possibility of the presence of another tuberculous focus, eliciting the positive ophthalmoreaction, can never be excluded, which, as it frequently happens, cannot be diagnosed."

W. O. Nance and Swift[5] make a similar statement, to the effect that the ophthalmoreaction is not a positive indication of tuberculosis of the eye, as the focus may be in some other part of the body.

C. Brons, cited by Zimmermann, states "that the tuberculous nature of an eye disease cannot be inferred from the course of the ophthalmoreaction. If it is severe or if the diseased parts participate in it, tuberculosis is probable; if it is mild it is no proof against tuberculosis. If the subcutaneous injection is followed by a positive general or local reaction" (which, by the way, Zimmermann claims should not be given after the ophthalmoreaction test) "the ocular affection is certainly tuberculous." Zimmermann points out some of the cases in literature of injury to the eyes from the ophthalmoreaction test; not only to diseased eyes, but even in healthy eyes, and gives a word of warning against its use as a test. Because of such disastrous complications after the Calmette test a number of ophthalmologists are entirely against its use. Stuelp[6] especially strongly advises against its use at all, and prefers for the diagnosis of ocular tuberculosis von Pirquet's cutaneous reaction, which in young children is especially valuable, and with the positive reaction indicates tuberculosis is present. If the reaction is negative and especially if repeated, tuberculosis may be excluded. In older subjects von Pirquet's test is not so valuable and the subcutaneous injection must be resorted to following it for diagnosis of active tuberculosis. On the other hand, if the von Pirquet test is negative the subcutaneous test is not necessary. Because of the many complications from the ophthalmoreaction, Zimmermann concludes his paper in the following words: "In view of these experiments ophthalmoreaction cannot be recommended and if the subcutaneous injection of tuberculin is not desirable the cutaneous method of von Pirquet may be tried, which in the very beginning of tuberculosis infection, especially for early childhood, is of inestimable value." Brons, Morax, Kalt, Zur Nedden, Torek, and others cited by Zimmermann prefer the subcutaneous test for tuberculosis. Of all the others Brons concludes that it acts with more certainty and ultimately through local reaction in the eyes confirms the tubercular nature of the affection. While Torek is of the opinion that, if after the subcutaneous injection of a small quantity of T. V. we have a general reaction, even though no local reaction takes place, in the suspected tubercular eye, we are justified in making a positive diagnosis of ocular tuberculosis, especially if the general condition of the patient and the local symptoms are indicative of tuberculosis.

From a résumé of the foregoing it may be concluded:

1. The ophthalmoreaction test (Calmette) is valuable as a diagnostic test for tuberculosis, a positive reaction from it indicating tuberculosis somewhere in the body, but not necessarily in the eyes. A negative reaction does not indicate the absence of tuberculosis, as in very young children (up to 2 years) and in advanced cases of tuberculosis the test often fails to give a positive reaction.

2. The opthalmoreaction test is not without danger even to healthy eyes and should never be used at all in eyes that have had old sites of inflammation or eyes with inflamed lids.

3. The initial dose should be small; less than 1 per cent. Koch's "old" tuberculin.

4. The cutaneous reaction test (von Pirquet) is a very sensitive test, especially in young children, where, if a positive reaction takes place active tuberculosis is indicated; while in older children and adults a positive reaction indicates tuberculosis either latent or active.

5. A negative cutaneous reaction, especially if repeated, is highly indicative of the entire absence of tuberculosis.

6. The subcutaneous test is considered by Brons, Torek, and others as the most reliable test for tuberculosis, and a positive reaction is a strong indication of active tuberculosis; furthermore, through local reaction in the eye itself tuberculosis of this organ is indicated.

7. The subcutaneous test should be used as a confirmatory test after von Pirquet's test, in adults, to make a positive diagnosis of active tuberculosis.

8. The subcutaneous test should not be used after the ophthalmoreaction test, as it is liable to reproduce the local reaction in the eyes, or to induce it if it has not occurred before.

Fracture of Patella.—Heineck summarizes the requirements of treatment as follows: The fracture must be reduced. The bony fragments must be maintained in intimate apposition until organic union has been effected. The continuity of the divided soft tissues must be reestablished. The functional integrity of the knee joint must be restored.—*Western Canada Medicol Journal.*

THE PECULIAR PROVINCE OF ERGOT.

By ALFRED T. LIVINGSTON, M.D.,

JAMESTOWN, N. Y.

After I had read before the New York County Medical Association the paper entitled "Some New and Unusual Therapeutic Applications of Ergot," one of the most noted of my auditors said to me, "Doctor, I can accept everything that you have said this evening except one thing. You said that ergot acts most pronouncedly upon the abnormal fiber. Now, if you can explain to me how ergot or any other drug can act more markedly upon the abnormal portion of the class of tissue upon which it has an influence than upon the normal portion of that same class of tissue, I will be greatly obliged to you." I replied that I regretted that I did not know the ultimate relation to, or action upon, the weak, relaxed, or stretched fiber, of the ergot which I had hypodermically introduced into the circulation, but that, in logical reasoning upon all the observations which I had made upon the effects of ergot in a great variety of malconditions, I could only conclude as I had stated, viz., that in its therapeutic application ergot had not markedly affected the healthy contractile fiber, but that it did always affect markedly and often marvelously those areas of that class of tissue which were in an abnormal state, weak, relaxed, or stretched.

Another of the noted practitioners of the Metropolis confessed to me that he had been inveigled into reading, late one evening, my first published paper, on "The Broad Therapeutic Application of Ergot," and that he had become so convinced that I was wrong that he had spent half the night in looking up his notes of the lectures of a famous professor of Materia Medica and that he had found that he had remembered them correctly, and that, therefore either I must be wrong or his teaching had been wrong.

One of my earlier papers was sent to the editor of a leading American journal by two gentlemen who had previously proven to their satisfaction the correctness of my statements as to the action of ergot, with the request that he would publish the paper promptly. The editor replied that he had read the paper and that he had been so astounded at its statements that but for the fact that those gentlemen had vouched for its author he would certainly have refused to publish the paper. At the urgency of one of these gentlemen I sent a copy of that same paper to each of two of the leading English journals and both copies were promptly returned with the apology from each editor of "lack of space."

I have premised thus to indicate the prejudice that existed against the conclusion which I had been obliged to deduce from logical reflection upon my experience.

There are several reasons for this strong prejudice. Ergot has belonged to the materia medica for centuries and it is natural that the profession should assume that its therapeutic virtues and fields of application must have long since been recognized. The teachings of authors and lecturers have been to the effect that ergot has but a limited field of application, which, indeed, is the necessary deduction from the generally accepted theory that it contracts the involuntary or unstriped muscle-fiber.

In the books and by lecturers a warning is always expressed regarding the grave danger of producing ergotism by its use in therapy. To several of my patients, traveling in Europe, druggists there have refused to sell ergot, telling them it was a rank poison.

I do not question but that the condition called ergotism has been caused by the eating of bread made from rye from which the smut had not been separated and I can accept that it may have been caused by some of the extemporaneously prepared potions, before the development of the modern extracts, but I do not believe that there is the shadow of a reason to continue to promulgate this malign innuendo against a most beneficent drug. While I have probably used as much ergot therapeutically as any other man, living or dead, in as great a variety of malconditions, in as large doses in certain cases and as long continued application in an individual case, I desire to put on record the statement that I cannot conscientiously say that I have recognized any ill effects from my use of this drug, given hypodermically, and I most certainly have seen nothing suggestive of the so greatly apprehended and dreaded ergotism. Yet even the manufacturers, by what I believe to be an utterly mistaken attitude toward this drug, not only damage their own business but, which is much worse, influence a large percentage of the medical practitioners against the use of the one drug which, in many of the most serious cases, might save the life of the patient.

One prominent pharmaceutical house has recently issued a most emphatic warning against the use of ergot in cerebral or pulmonary congestion or hemorrhage, basing the deduction to this effect upon "laboratory experiment." Basing *my* statement upon thirty-six years of medical practice, during which I have made use of ergot in all sorts of variations from the normal distribution of the blood, I do not hesitate to say, and will rest my reputation, present and future, upon this statement, that there are no other two regions of the body upon which a proper preparation and dosage of ergot, hypodermically administered, has had or will have more therapeutically beautiful and desirable effect than those of the brain and the lungs. Especially is this true as to states of congestion in those regions.

With these regions vies that of the abdomen as to the supreme indication for ergot, especially in relation to those disturbed states of the circulation which impede the action of the heart, which, of all the organs of the body, is probably the most irrationally and outrageously treated by the profession today, if I am to judge the profession in general by those lights which so often shine upon the public in relation to patients of wealth or position who, supported by strychnine, glonoin, salt solutions, *et al.*, "pass on" under the certificate "heart failure."

The region of the pelvis would come after the others mentioned, in the matter of importance or frequency of indication for ergot, and, of the chief organs of the pelvis, that one would probably come last which for centuries was the only organ of the body upon which ergot was used.

I have said advisedly a proper preparation of ergot. The fact, which I will further assert, that it is *not* the normal tissue of the body upon which we desire the influence of ergot in treating the sick, and another fact that I have observed in my experiments with those preparations of ergot from which the manufacturer claims that the inert (?) elements of the drug have been expunged, viz., that there has not been demonstrated that degree of therapeutic efficiency which the manufacturer has implied from

his physiological tests, have led me to question the propriety of such methods of standardization of this drug and I am free to say that I distinctly prefer, because I have found them the most effective, those preparations of ergot which most nearly represent the drug.

The assumption involved in the physiological method (experiment upon normal tissue of animals) of determining the therapeutic efficiency of ergot is practically the same as that made by the gentleman whom I first quoted, viz., that all drugs must have their most marked effect upon the normal tissue of the classes which they influence. That this assumption cannot apply to ergot would seem to be sufficiently indicated in the fact that, when applied to a pathological case, it is only upon the abnormal unstriped or other contractile tissue that a proper preparation of ergot demonstrates its peculiar power, which is to restore to or toward the normal that which was below the normal.

Were it true that ergot has its supreme action upon the normal contractile tissue, there is not a single instance in which I have applied it in which there would not have resulted a worse state than existed before its application. For example, the vessels of a congested area contain too much blood; this fact implies a relatively lessened contractile power in the walls of those vessels, as compared with the vessels not congested; the vessels not congested are relatively normal and the congested vessels are abnormal. Assuming that the physiological test does determine the efficiency and that ergot, as is claimed for other drugs, acts most vigorously upon the normal contractile tissue, what will be the result of applying a dose of ergot in a case of congestion? The vessels which are not congested will be contracted more, relatively, than the congested vessels and some of the blood which has occupied the former will be forced into the congested vessels, resulting in a greater congestion than had existed before the ergot was applied. The *fact* is that the assumed result does *not* occur and the inference which I am obliged to deduce from that which *does* occur, viz., the contraction of the congested vessels, is that the assumed theory is wrong.

Were it true that ergot acts most vigorously upon the normal contractile tissue, it must follow that ergot will always raise blood pressure. If the reader will refer to either of my first three published papers* upon the therapeutic action of ergot, he will find the relation of the case of the old man in Philadelphia. I have surely never seen a more extreme case of arterial tension, and the result of the application of one ordinary syringeful of ergot was the changing, within a few minutes, of a sledgehammer pulse to one of the softness of a baby's.

A young doctor of a Johns Hopkins clinic class wrote to me asking whether ergot had the effect of raising the blood-pressure or of lowering it, stating that there were opposite opinions among the members of the class. I replied at some length and with great care explained how in some cases ergot would raise the blood pressure and in other instances would lower it, yet having in each instance precisely the same effect upon the abnormal contractile tissue of the circulation. As, for my pains, I had not even the courtesy of an acknowledgment of my letter, I inferred that the young man had set me down as unworthy of further consideration because I had made the same drug to appear to "blow both hot and cold." Nevertheless this is the exact truth, and the explanation of the apparent contradiction is the differing combinations of areas of abnormal unstriated fiber, or other contractile tissue, which have produced the opposite sets of symptoms.

If the cause of a too high blood pressure is an irritation to the heart, central or reflex, producing over vigorous pumping into the arteries, or is a great venous stasis against which the heart is vainly exerting, ergot, by relieving the congestion which has produced the irritation, or by contracting the overdilated veins, will reduce the blood pressure. If the heart pump is weak from a general exhaustion, the heart walls stretched and thin, or if there is so great a distention of the splanchnic veins that there is but little blood left to pass through the heart and arteries, as is the state in syncope, collapse, so-called heart-failure, and shock from trauma, operation, or anesthesia, the blood pressure is lowered and it will be raised if ergot is hypodermically administered, because this drug will not only tend to normalize the weak and stretched heart fibers, but it will contract the engorged abdominal veins and so restore to the arterial system the quantity of blood which it should have.

In all such cases it is eminently rational to apply ergot to produce the effects just stated and it is quite as eminently irrational in such cases to prod the heart with strychnine or like irritants, without taking the one simple and efficient therapeutic step to correct the real and basal trouble.

To whatever extent there exists an abnormal disturbance of equilibrium of blood distribution, to that same extent there exists a variation from the normal blood pressure for that individual, and a variation from the normal heart action. Whoever, in the cases of so-called "heart failure," will limit his therapy to ergot only, will soon recognize that heart failure *per se* is a mighty rare condition; and that, instead of pelting the poor heart when it is weak and failing, the real and paramount indication, in the vast majority of the instances of threatened fatality, is the relief of the heart from those obstacles to ease and freedom of its action, which exist in states of abnormal vascular distention, both venous and capillary.

I once listened to the reading of a paper upon angina pectoris by a noted doctor of a neighboring city. I had mentally resolved not to take part in the discussion of it, because I felt that my silence would appear more harmonious to our guest than my speech, but as I was directly called upon to speak, I said what I believed. I was not quite prepared though for the denouement, for the moment that I mentioned ergot as, in my judgment, the desirable treatment, the reader of the paper, not waiting until the close of the discussion, nor even until I had finished my remarks, instantly arose and exclaimed with great emphasis, "Of all drugs, *that one* is the most contraindicated in angina pectoris!" He did not know that another famous practitioner, he who had spent half the night in verifying his impression that I must be wrong in my theory as to the action of ergot, had, on the morning following that night, proven my theory by using ergot in a case of angina pectoris "as a last resort and in sheer desperation" after having vainly tried every other treatment of which he knew, and within ten minutes the patient, who had been long in agony, sitting in a

**New York State Journal of Medicine,* September, 1902; *Journal American Medical Association,* March 21, 1903; *Brooklyn Medical Journal,* August, 1903.

fixed and constrained attitude, took a deep breath, settled back and remarked "I feel *comfortable* now."

That was the first of a long series of cases and great variety of conditions in which that practitioner proved my statements, and I have heard him say five or six times, in the discussion of as many of my papers, that he believed every word that I had said. This sweeping support of my asseverations was doubtless suggested by his recognition of that one truth which has been the theme that runs through all that I have written concerning this drug, viz., that the normalizing of the abnormal (weak, relaxed, or stretched) unstriped fiber or other contractile tissue is the peculiar province of ergot.

I have not attempted to explain, for the simple reason that I have not known the ultimate relation of ergot to the abnormal contractile tissue, just how it normalizes it, nor why ergot does not notably affect the normal tissue in a pathological case. It has been sufficient for me that I have clearly recognized and demonstrated and have unequivocally expressed the fact.

I have left to the profounder students of ultimate pathology the explanation of this peculiar therapeutic action.

Dr. Homer Wakefield, of New York, was one of the first to confirm my published views upon the action and province of ergot. From his studies he had come to like conclusions to my own regarding the relation of disordered states of the distribution of the blood to functional and organic disorders of the heart, and he was searching for better means than he had possessed to empty engorged splanchnics, to draw to the surface the excess of blood in the storage vessels—in other words, to restore normal general blood distribution. Upon hearing my first New York paper he found this desideratum in ergot. In his development of a scheme of general pathology he has at the same time made apparent the only rational explanation of the *modus operandi* of the action of ergot that I have encountered.

There are three qualities of tissue that are especially concerned in this explanation, viz., density, equilibrium length of fiber, and sensibility. Density and sensibility are self-explanatory. "Equilibrium length" is the length of fiber in the state of physiological rest. The processes of change from the normal are gradual to a point at which the possibility of function ceases. Up to that point, in the instance of such tissue as is affected by ergot, there are gradations from the normal in lessened density (which implies a greater porosity and increased capacity to absorb), in increase of equilibrium length (which implies weakness proportionate to such increase), and in increased sensibility (tissue hyperesthesia).

The hyperesthetic state and the more absorbent (osmotic) quality of the less dense and elongated fiber determine the application of the ergot to those altered tissues.

It will be seen that this explanation also covers that tissue (not technically abnormal, but physically similarly altered) upon which was first observed the effect of this wonderful drug, viz., the greatly elongated fibers of the gravid uterus. No one questions the effect of ergot in shortening the equilibrium length and increasing the density of the stretched uterine tissue.

The obstetrician is no better assured of the efficacy of ergot in contracting the stretched fibers of the womb, than am I of its like efficacy to normalize the weak, relaxed, and stretched contractile tissue of blood-vessels anywhere in the body (brain included), of the heart, of the bowels, and of the hollow viscera. I have never claimed for ergot that it will bring the dead to life, nor do I maintain that it will restore to the normal such tissue as has degenerated beyond the point indicated above, the possibility of functionating.

The technical statements in connection with the explanation of the action of ergot are vouched for by Dr. Wakefield and they certainly harmonize with and tend to corroborate all that I have claimed to be the peculiar province of ergot.

ANATOMICAL HEREDITARY PECULIARITIES AS AN ETIOLOGICAL FACTOR IN DEFLECTED NASAL SEPTA AND ACCESSORY SINUS DISEASE.*

By J. G. WILSON, M.D.,

ACTING ASSISTANT SURGEON U. S. P. H. & M. H. S.; ASSISTANT SURGEON N. Y. THROAT, NOSE AND LUNG HOSPITAL.

THE mammals are remarkable for the degree in which the sense of smell is developed. The large extent of pituitary surface, and the large size and number of olfactory nerves are mammalian characteristics. Although this general statement holds good in the majority of species, we have numerous exceptions. In the *Delphinidæ*, of which the dolphin and porpoise are representatives, we find no olfactory apparatus at all.[1] In the herbivora and ruminants the sense of smell is most highly developed and the bones of the face preponderate greatly over the brain case. In regard to the acuteness of the sense of smell both man and monkey are inferior to most other quadrupeds. The progress in the development of the sense of smell is, therefore, not *pari pasu* with a general rise in the scale, as is the case with the sense of taste.[2]

Passing from a consideration of animal forms to that of the lowest type of primitive human skulls available, we have evidence to show that the brain case is developing at the expense of the bones of the face, and that the olfactory apparatus is becoming more and more encroached upon as the type of the species improves. This relation of the facial to the cranial capacity is expressed in degrees of the facial angle. This angle, as described by Owen, is formed by the intersection of two lines, one of which is drawn from the occipital condyle along the floor of the nostril, to the most prominent point of the upper jaw, and the other of which extends from this latter point to the most prominent point on the forehead. This angle varies greatly. In the dog it is 20 degrees. In the gorilla, 40 degrees. In the Australian, 40 degrees, while in the educated white man we may expect to find it more nearly approaching the perfect type of the Grecian ideal, that is, 100 degrees.

The preponderance of face over cranium in the lower mammals is explained by the fact that in these forms the bones of the cranium cease to grow at an early date, whereas the facial bones continue to develop up to adult life.[3] A study of figures 1 to 7 will show how, in the lower forms of vertebrates, the bones of the face are developed at the expense of those of the brain case, until we come to the gorilla, where the facial and cranial capacity are about equal. In the lower forms of the human type

*Read at the regular meeting of the Clinical Society of the New York Throat, Nose, and Lung Hospital, October 6, 1909.

the facial and cranial equilibrium is still fairly well maintained, but in modern civilized man the tendency of the brain case to develop at the expense of the bones of the face is constantly making itself shown. The effects of this relative overdevelopment of the brain case is manifested in the following ways: (1) The recession of the jaws; (2) The gradual disappearance of the accessory sinuses; (3) The prevalence of deflected nasal septa.

The recession of the jaws is responsible for many pathological conditions of these appendages. The diminished space for the development and eruption of the teeth, leading to overcrowding and irregularities, the inability to approximate accurately the two maxillary surfaces, thus leading to mouth breathing and the improper mastication of food, are all conditions well known to the orthodontist.[4] The natural and gradual recession of the jaws which is going on in the white races is also shown in the prognathous negro race as a result of crossing with the white.

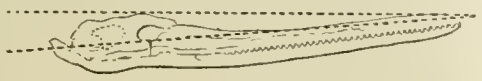

Fig. 1.—Crocodile (Owen).

Boas has shown that when race intermixtures take place, there is a strong tendency to reproduce ancestral traits.[5] In the case of the mulatto we would, therefore, expect to find many instances where the jaws were more receding than in his negro ancestor. That such is the case and that its frequency is increasing as time goes on has been conclusively shown by Talbot.[6] He states that out of many hundreds of negros examined in the lower Mississippi valley 97.5 per cent. showed marked prominence of the lower jaw. Out of 1,000 negroes examined in Boston, 45.4 per cent. corresponded to the type where the point of the chin fell behind a perpendicular line drawn from the most prominent portion of the forehead at right angles to the base line of the skull. The inference from this is plain. The recessive type of jaw is dominant, and wherever the cross between white and black takes place to any appreciable extent, we may expect to find many examples of conformity to this type among the mixed offspring.

Fig. 2.—Albatross (Owen).

Pari pasu with the recession of the jaws, we find the accessory sinuses giving place for more brain development. In those vertebrates in which the sense of smell is highly devloped the accessory sinuses are large, and afford room for the ramifications of the turbinal scrolls, and consequently indirectly contribute to the space for the distribution of the olfactory nerve filaments. The enormous development of the middle turbinate in the dog is intimately connected with his acute sense of smell.[7]

In man only the upper portion of the middle turbinate is supplied with olfactory nerve filaments, and there are no ramifications of the turbinal bones into any of the accessory sinuses. In the dog there are scroll-like filaments of this bone in all the sinuses, even in the frontal and the sphenoidal. That the accessory sinuses in man subserve any specific purpose is highly problematical. Some authors have stated that their function is to give more resonance to the voice, but this is probably only an accidental quality which they possess, and can hardly be looked upon as the result of any selective action on the part of nature. The argument sometimes advanced that they serve to increase the space or bone surface available for the numerous muscle attachments of the face, and have, therefore, been developed for that purpose, will not stand the test of close reasoning. The other bones of the body whose surfaces are obviously increased for the sole purpose of providing additional space for muscle attachment are filled with a cancellated structure rich in fat and blood-vessels, their nourishment being thus amply provided for, and their resistance to pathogenic germs reduced to a minimum. If a selective process with exactly the same end in view had taken place in the bones of the face, it seems difficult to understand why the same result would not have transpired here as in the ends of the long bones. Identical ends in different parts of the body are attained by identical methods, and there seems no good reason to suppose that nature has made an exception in the case of the accessory sinuses.

In the human embryo there is a complicity of accessory sinuses and nasal fossæ which subsequently disappear.[8] A study of these sinuses in primitive man is instructive. Here the evidence is all in favor of a former great development in comparison with that found in modern man. Huxley, in commenting on the characteristics of the Neanderthal skull, quotes Schaafhausen as remarking upon the extraordinary development of the accessory sinuses which it presented.[9] Schaafhausen did not consider this to be an individual or pathological deformity, but a typical race characteristic.

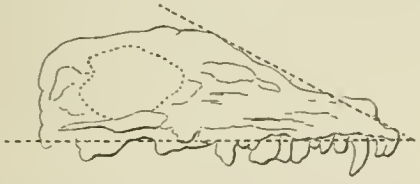

Fig. 3.—Dog (Owen).

The consensus of opinion seems to be that the North American Indian and Eskimo have unusually developed accessory sinuses. Hrdlicka, who spent much time among the Indians of the southwestern United States and Mexico, and made many accurate observations of their physiological and anatomical peculiarities, subscribes to this belief.[10] An examination of ninety-one crania in the Museum of Natural History in New York City was undertaken with the idea of ascertaining if there existed any uniformity in regard to the size of the cells in primitive man, and whether or not they were universally large. Of these crania twenty-six were northwestern coast Indians from Vancouver island, two were from Wisconsin tribes, eleven from Alaska, thirty-one were Eskimo, thirteen were from Ohio and Kentucky mounds, seven were Peruvian Indians, and one was from the Yaqui tribe. On account of the peculiar anatomical characteristics of the sinuses, it is impossible to take accurate measurements of their capacity without making cross-sections. This was not possible, but the general result of the observations leaves the impression that there was a much greater development than is commonly encountered in the case of patients presenting themselves at our clinics for treatment.

The sphenoidal cell admits of accurate measurement of its anteroposterior diameter in the dried skull, without any dissection or any cross-section sawing, this measurement taken in the ninety-one cases referred to, ranged from three-eights to one and one-half inches, with a mean of sixty-four one-hundredths inch. The medium was five-eights inch. The standard deviation, nine hundred and thirteen ten-thousandths of an inch, with a probable error of six hundred and fifteen ten-thousandths. Although the number of crania examined may seem too few on which to base conclusions, the fact that the median variation so closely approximates the mean, and that the fraction of probable error is small, would lead one to believe that a sufficient number had been measured to form a fairly accurate opinion as to the average depth of the sphenoidal cell in primitive American types.

Eleven specimens of modern skulls showed an almost equally wide range of variability, the smallest being one-half inch in diameter and the largest one and one-eighth inch. The number of skulls examined is not sufficient to warrant the forming of comparisons between the capacity of the sphenoidal cells in primitive and modern man, but the extreme range of variability in both cases counts strongly in favor of the argument that these cells are undergoing developmental changes common to those organs which no longer subserve any specific useful purpose to the organism.

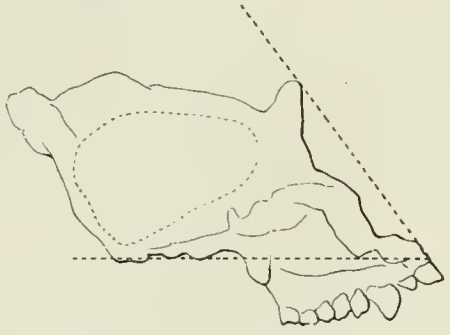

Fig. 4.—Gorilla (Owen).

Although the accessory sinsuses in man are not at the present time in any way contributory to an increased acuteness of the sense of smell, their size and development seems to bear some relation to the acuteness of that sense. Humboldt[11] noted the highly developed state of the olfactory sense among the South American Indians, and it has been proven by experiment that negroes and Indians are often able to recognize individuals by their odor.[12] The fact that certain savages are apparently insensible to bad odors does not at all invalidate the truth of the proposition that their sense of smell is more highly developed than in civilized man. Whether an odor is pleasant or disagreeable is largely a question of individual taste, and depends more upon the habit of the individual or species than it does upon the degree of acuteness of the sense in question. The fox, which is a remarkably keen-scented animal, lives habitually in dens which are extremely foul smelling to us. The hog, which has also an acute sense of smell, seems to be entirely oblivious to the odor of putrid flesh.

As the accessory nasal cavaties deviate more and more from the primitive type their liability to disease correspondingly increases. Among the modern civilized races both chronic and acute sinusitis are very prevalent. The frequency of their occurrence seems to be in no way dependent upon any particular kind of climate, or geographical locality. It would seem that chronic suppurative conditions of these sinuses often exist without giving their possessors much apparent trouble. In a pamphlet published by Martin he tabulates the results of seven hundred and forty-six autopsies in which the accessory sinuses were examined. In the seven hundred and forty-six cases there were found evidences of chronic sinusitis in two hundred and forty-nine instances.[13]

Whereas the evidence is ample that affections of these cells are very common among Europeans and Americans, there seems to be an entire lack of testimony to show any thing like an equal occurrence among primitive races. The Indian and negro, and Australian aborigine, are practically free from troubles of this kind.

As the negro in the United States is undergoing a gradual change owing to intermixture of white blood, we should expect to find instances in which the facial development—and capacity—of the accessory sinuses would correspond to the white parental type. Hence, affections of these sinuses should be, theoretically, more frequent in mulattoes than in full-blooded negroes.

In regard to the third manifestation of relative overdevelopment of the brain case, namely the deflection of the nasal septum, we are confronted with so many other theories of its causation that we must first analyze the various explanations advanced, and see wherein they fail to account for the condition, before we bring forward the positive evidence in favor of our own hypothesis.

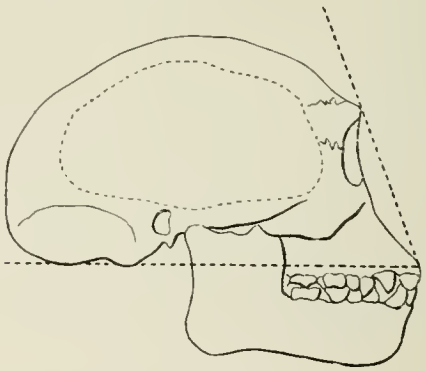

Fig. 5.—Pithecanthropus erectus (Dubois).

At first thought the most rational explanation of deflected septa is mouth breathing, caused by adenoids. According to this theory, the mouth breathing child lacks the support and lateral pressure exerted by the tongue against the alveolar processes of the superior maxillary bone, thus allowing the palate to become high and narrow, and thereby encroaching from below upon the perpendicular space available for the development of the septal bones and cartilage.[14] This is the commonly accepted view of its causation. That this is not the primary cause is conclusively shown by the fact that the percentage of deflected septa among those races which are not mouth breathers, and who do not have adenoids, is almost as great as among our own people. Hrdlicka states that a more or less deflected nasal septum is very common in the Indian. A perfect septum being one of the greatest rarities. At the same time he states that they are much more free from catarrhal affections than is the white man, and that mouth breathing is not at all common

among them.[15] Of sixty-four dried skulls of primitive man examined at the Museum of Natural History in New York City, nineteen marked deviations of the bony septum were found. This is a frequency of thirty per cent., and must necessarily be an underestimate because of the fact that only bony deviations were observed. Cartilaginous deviations are much more common, but in the dried specimens the cartilage is usually lacking, and therefore has to be left out of the count.

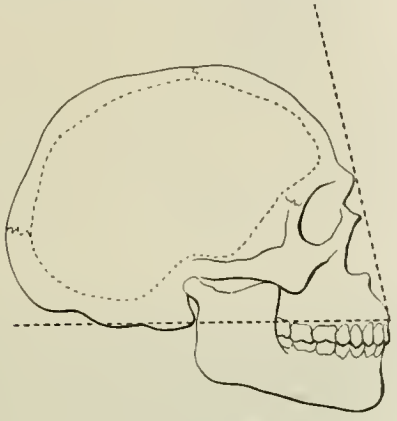

Fig. 6.—Australian savage (Owen).

That the Southern Italian and Sicilian are much more free from adenoids and mouth breathing than the narrow nose races of Northern Europe and the United States, is a matter of common knowledge, and yet deflected septa are prevalent among them. Of ten hundred and eighty-six South Italian immigrants examined without a speculum there were eighty-seven or eight per cent. found with marked deviations of the cartilaginous septums. Of 1044 narrow nosed Northern European immigrants, including over 600 Scotch and Irish, all of which were examined in the same way and under the same conditions as the Italians, there were 93, or 8.9 per cent., found with marked deviations of the cartilaginous septums. Here we find practically the same result in two classes of people which are entirely opposite in respect to the prevalence of mouth breathing. The occurrence of deflected septa seems to be pretty clearly established among all races of people. The difference means simply this, that in the narrow nosed races a deflected septum so nearly approaches the turbinate on the side of its covexity that the slightest coryza or irritation is sufficient to produce a congestion which will cause contact with the mucous surfaces, thus giving rise to nasal obstruction and mouth breathing. This quickly leads to a condition of negative atmospheric pressure with a resulting hyperemia of the nasal pharynx, which in turn causes the adenoid tissue there normally present to undergo hypertrophic changes; thus rendering worse or entirely complete the obstruction for which the septal deviation was primarily responsible. A sort of vicious circle is now established, and as a result of the mouth breathing and loss of the lateral support of the tongue, the arch of the palate becomes high and the septum, which was at first only slightly deviated, becomes more and more deflected until its development ceases with the advent of early adult life. In the wide nosed races, on the other hand, it takes a very marked and unusual degree of septal deviation to produce contact with the mucous surfaces and a consequent congestion of nasal obstruction. Thus it is, that although deflected septa are as a matter of fact prevalent among negroes, Indians, and all wide nosed races, they rarely produce pathological conditions in these peoples and have consequently been overlooked by a majority of observers.

Another theory to account for deflected septa is that they are due to irregularities of development caused by mingling of distinct racial types. The recent work done in investigating the laws governing heredity would seem to discredit this theory.[16]

As stated before, Boas has shown that when two races intermingle the half-breed product serves to reproduce one or the other of the ancestral unit characters rather than a cross between them.[17] From the standpoint of the antropologist the Southern Italian is one of the purest races of which we have cognizance,[18-19] yet we have seen the prevalence of deflected septa among them to be almost equal to those of the races of Northern Europe, which are the result of the intermixture of many different types.

Whatever opinion one may hold as to the racial unity of the Jews, considered as a class, there is very little doubt but what those coming from Russia and Southeastern Europe have maintained a high degree of blood purity for a great many generations.[20] The extreme prevalence of deflected septa among the Hebrews coming from this part of Europe has been shown by Glogau. Out of 4400 cases which he examined at Mt. Sinai Hospital he found 3823 deviations.[21] Fishberg, who has made anthropological investigations among the same class of Jews from which Glogau's statistics are compiled, is authority for the statement that the width of the Hebrew nose is usually less than 70 per cent. of its height.[22] A nasal index of 70 per cent. must place its possessor among the distinctly narrow nosed races.[23] Hence, the slight septal deviation which is almost universally present among all races readily becomes pathological in the Jew on account of his congenitally narrow air passages.

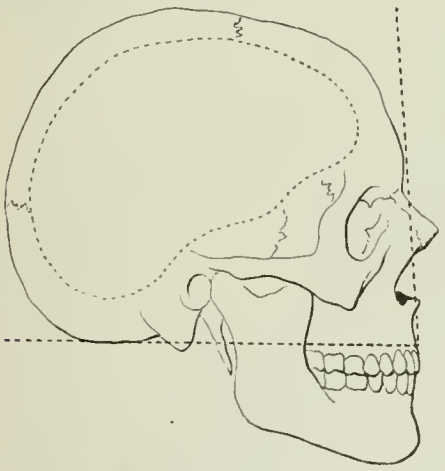

Fig. 7.—Modern civilized man (Owen).

Thus, we see that the theory of race intermixture as the cause of deflected septa is not only contrary to what we know of the laws governing heredity but actual observation also fails to establish it upon a firm foundation.

The theory that the primary cause is due to prolonged pressure during parturition can have no foundation in fact from the simple reason that primitive races show a large percentage of deflected septa notwithstanding the ease and rapidity of labor among them.

The real cause of this condition is probably to

be found in the relative overdevelopment of the brain case in comparison to the bones of the face. In the human embryo the parietal, frontal, and occipital bones, together with the superior maxillary, palate, nasal, and ethmoidal, commence to ossify about the seventh week of fetal life. The vomer does not show any center of ossification until about the sixth month.[24] Thus we see that very early in life the space for the development of the septum is being impinged upon by those bones with which it articulates. As the infant grows older the pressure on the septum from above rapidly becomes more marked on account of the great growth of the bones comprising the brain case. In the lower animals growth of the cranium ceases at an early age, while the bones of the face develop up to adult life.[25-26] Whereas the process is not exactly reversed in man, nevertheless there is a continuance of the growth of the cranial bones up to the time of the cessation of cerebral growth, which is usually about the age of thirty years.[27]

Thus the process of deviation which begins in infancy is hastened by a lack of correlation between the growth of the nasal bones and those comprising the cranium, and it is in the relative overdevelopment of the latter that we find the fundamental cause of deviated septa.

From the foregoing observations I think the following conclusions may be fairly deduced:

1. The accessory nasal sinuses do not at present subserve any specific useful purpose, but are to be classed among the disappearing or vestigial organs, which facts largely account for their susceptibilty to infection.

2. The presence of deviated nasal septa is probably equally common in all races, becoming pathological only in those races which are congenitally narrow nosed.

3. The cause of congenitally narrowed air passages and deviated septa is primarily developmental, and finds its true explanation in the fact that the brain case is being developed at the expense of the bones of the face and olfactory apparatus.

SPONDYLITIS DEFORMANS.*

WITH A REPORT OF SEVERAL INTERESTING CASES.

By SIGMUND EPSTEIN, M.D.,

NEW YORK.

CLINICAL ASSISTANT, ORTHOPEDIC DEPARTMENT, VANDERBILT CLINIC.

Spondylitis deformans having interested a large number of observers in the past few years, serves as a motive for my bringing the subject before you this evening. Called by French observers *spondylose rhizomelique,* it is essentially an ankylosing inflammation of the spine, chronic in its course, progressive in its disabling effects, and accompanied by painful symptoms. Predominance

Fig. 1.—Case 2, boy of 16 years; showing marked lordosis and prominence of the scapulæ.

of characteristic symptoms and ensuing deformities leads to the classification into a number of types. To begin with, there may be simply a stiffness in the back, without much bony change.

Case I.—Mrs. G., 65 years of age, consulted me for longstanding pains in the knees and ankles, besides a stiffness in the lower part of the back. She had tried treatments by naturopaths, electricity administered by her family physician, and visited various spas without result. The lower dorsal and lumbar spine proved, upon examination, to be ankylosed, while the motions of the hip were restricted

*Paper read before the Richmond County Medical Society, New York, June 9, 1909.

in flexion and abduction. Treatment: Strapping of the back, proper shoes, and a diet chiefly of buttermilk, gave a fair measure of relief.

This was a mild case, of a type that is frequently seen in neurasthenic patients. In the more marked cases, we notice the peculiar deforming action of

Fig. 2.—Case 3, Spondylitis deformans, with bow-back; a temporary adhesive strapping has been applied.

periosteal and bony hypertrophy. The ligaments and interarticular cartilages degenerate. The new formation of bone tissue, so characteristic of osteoarthritis, takes place on either side of the body of the vertebra, and extends down the spine; one segment after the other is affected, until we have a mass of newly deposited bone, sheathing the column as if one had poured thick syrup from above, and let it crystallize. The vertebræ are usually lipped at their edges, and they soon fuse together, forming the "poker-back." If there be much proliferation along the lateral aspects of the spine, the process may encroach on foramina of exit of the spinal nerves, causing pain along their areas of distribution, disturbances of sensation, and occasionally paralyses. Herpes zoster and symptoms of meningeal irritation have been observed. *X*-Ray plates demonstrate a compact fusing of bony trabeculæ. The microscope shows evidence of extreme density, in that the lamellæ are packed closely together. As to deformities, most of the cases belong to the type of the "long round back"; scoliosis can occur, however, from enlargement of one side of the body of a vertebra. Lordosis is quite unusual.

Etiology: Injuries are often described to be the starting point of the disease, but it has been difficult to demonstrate a direct relationship in most of the cases I have observed. The majority are past the prime of life and of the male sex; day laborers, coming for treatment for backache, will mention that the deformity has existed for long periods, without inconvenience. Gonorrhea has been antecedent in a fair number of cases coming under the observation of Bradford of Boston. I believe that in many instances gonorrheal rheumatism leaves the spine stiffened, and certainly every one has seen backaches in chronic polyarthritides of urethral origin. I have seen three cases of intractable backache complicating gonorrheal exostoses of the heels.

The types of the disease are: (1) Bechterew's, in which the other joints are not generally affected, and in which a neuropathic connection is supposed to exist; (2) the Strumpell-Marie type, combining ankylosis of the spine with that of the shoulders and hips. These vary so that they really merge into each other. Cases appended belong to either type.

Symptoms: The peculiar spinal stiffness seen in spondylitis deformans is at first due to muscular irritability, later to true ankylosis. During an acute attack the functions may be so disturbed as to render the column entirely rigid. Later a considerable part of the muscular spasm may have passed off, excepting a more or less extensive area of residual stiffness—that of bony fusing. Forward bending is awkward or impossible, the trunk bending as if it were an iron poker from sacrum to occiput. The testing for lateral mobility gives striking results; at first being limited more to one side than the other; later progressing stiffness is observed. One may find a lateral deviation, or the physiological dorsal curves may be so increased that the lumbar (forward) curve is obliterated. The whole spine forms a bow with its convexity

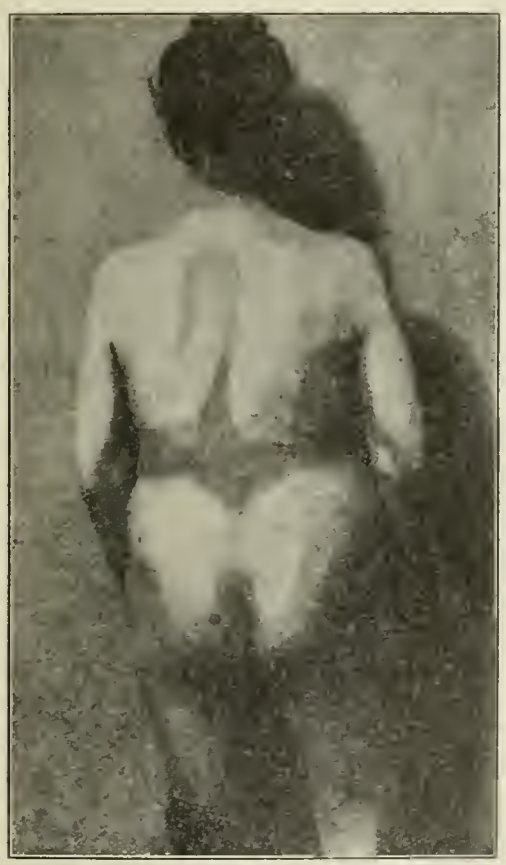

Fig. 3.—Case 4, spondylitis deformans; kyphoscoliosis; the fold in the abdominal muscles seen on the right side extended anteriorly across the abdominal wall.

backward—"the bow-back." Another common deformity is a straight, boardlike back. The gait is stooping, with the body bent forward, motion being entirely from the hips. Should the hips be involved, the body weight must be alternately shifted from one side to the other, the gait becomes

a disabling waddle, and patients find canes necessary in going about. In the reclining position the curves are not obliterated. The lower portion of the spine is generally first affected, the cervical portion becoming the seat of a subsequent attack. In severer cases the ribs are ankylosed at their junction with the spine, the chest wall scarcely moving during respiration. On attempting to turn around, in the standing position, the individual uses his heels as a pivot. Pain may be localized in the spine, at or around the spinous processes; it is often referred to the hips and shoulders, from impingement of the bony growths on the neural exits. This explains some of the miraculous "cures" of pains in thighs and calves, brought about by the effective "wiggling" of the spine by osteopaths. The figurative lengthening of the patients' legs from pulling thereon, seems to be a common sequel. This backache, neuralgic in character, "like a toothache," is usually more marked to one side. It may be increased by jarring on the heels. Marked tenderness over the spinous processes is the rule. The pain is always accentuated by active work, and relieved by resting.

Differential Diagnosis: In lumbago, there may be muscular spasm, but mobility of the spine is not long nor gravely limited. Sciatica is a disease limited to the nerve and its trunks in the sacroiliac region, and although there is frequently a scoliotic curve, there is no limitation of the spinal motion. Diseases of the hip, such as tuberculosis and malum coxæ senile, have their peculiar .r-ray appearances, a mobile spine, and physical signs in the hip. Spinal conditions to be cast aside are: Pott's disease (with its usually angular kyphosis, tuberculous lesions elsewhere, and the positive reaction to the various tests), aneurysm, and malignant disease. Sacroiliac disease furnishes tenderness and swelling localized to the sacroiliac joint, plus marked stabbing pain on attempting Goldthwait's maneuver of flexing the thigh on the pelvis while the leg is straightened. Pott's disease is usually the difficult problem for the diagnostician to eliminate, but abscesses will assist in the exclusion, while time, too, will help—referring to a short expectant period in which the patient wears appropriate immobilizing appliances. Diseases of the mesenteric nodes would present abdominal symptoms.

The prognosis, in early cases, is favorable as to complete recovery, a quiescent stage supervening under prompt and proper treatment. If the case is a progressive one, or if other joints are affected, the condition is a problem of patience, on account of the relative impossibility of complete cure. If both hips be implicated, as is occasionally seen, the patient's disability is marked, and the outlook is doleful.

Treatment: Under general measures we force the patient to stop his work, and instruct him to lead the simple life. We encourage the liberal use of water by approved methods. Exercise in the open air is ordered, and fatigue avoided. Thermal baths may be of benefit, but electricity is of no avail. The rigidity and pain have positive indications for fixation and protection of the spine, there being always an annoying exacerbation after any traumatism. We see in fixation a prevention, not only from stimulation of the proliferative process, but from the painful jarring of bone or osteophyte against sensitive nerve filaments incident to bending or twisting. Fixation is best furnished by a plaster jacket. This should be applied with the patient standing, slightly extended by the Sayre suspension apparatus, the desideratum being fixation, at first, rather than correction. As the acute symptoms abate, in four to six weeks, a second jacket is applied. It is good management to remove this in about eight weeks, and continue the fixation with a third jacket. At this time an improvement will be noted, the pain having practically disappeared. The spine will be found to be less rigid, and on examining for muscular spasm, the peculiar twitching that had previously been noted, on hyperextending the back, will be conspicuous by its absence. A brace, known as the "spinal assistant," is now accurately fitted to the spinal column, and worn as long as there is any evidence of irritability; this being a disease in which the patient has his "ups and downs." In certain cases, manipulation, massage, and active motion has proven of a great deal of assistance in my experience. Bradford believes that "the use of manipulation to ward off the approaching ankylosis is harmful and undesirable at all stages of the affection." I well remember one patient who always felt better after a session of rubbing, in which the masseur jumped on him, and bent him almost double. Palliative treatment, with the cautery, followed by strapping of the back, is temporarily of great benefit in selected cases. The management of a large number of instances of this condition has firmly convinced me of the efficacy of resistance exercises, accurately regulated by the Zander machines. Thyroid extract is to be recommended.

Case II.—L. F., 16, Austrian. Arthritis deformans, spinal, sarcoiliac, and coxitic (Fig. 1). Father died of tuberculosis. Boy walked at the age of two years. Was able to run about as other children. Noticed stiffness of back only during past year, gradually getting worse. Now complains of pain over the right hip, worse at night, and of difficulty in walking.

Physical Examination, Sept. 16, 1908: walks with marked waddle, body being inclined to the side at each step, on account of disability at the hips. There is a marked lordosis, and the abdomen is prominent. Boy is thin, skin seems darkly pigmented, while mucous membranes are somewhat pale. The spine, from the last cervical to last sacral vertebra, forms a long lordotic curve. Stiffness in this area is absolute; side bending impossible in either direction. No tenderness; no lateral deviation. Over the sacroiliac joints a number of osteophytes are palpable. These are rounded, the size of peas, probably form a synostosis of the articulation. Hips: all motions are limited, to some extent, especially adduction. The visible apex thrust against the left thorax is striking. X-ray findings: The lumbar spines show ankylosis of the articular processes, ossification of the intervertebral discs, and light shadows of large osteophytes above the sacroiliac joints, as well as to the sides of each vertebral body. Blood count, RBC, 5,000,000; white cells, 11,000; hemoglobin, 80 per cent. Treatment, a light spinal brace has been worn with a great deal of comfort. The stiffness of the hips, which skiagrams showed to be due to osteal outgrowths about the acetabular rim, has been somewhat improved by systematic use of the hip machines, that have been installed during the past year at the clinic. A recent examination demonstrates a small range of motion in the dorsal region of the spine, a decided improvement in the gait, as well as the general appearance.

Case III.—Mrs. Lizzie G., 27, married, Russian.

Spondylitis deformans, chronic nephritis (Fig. 2).

Past History: At the age of sixteen, suffered from nephritis, with attacks of kidney insufficiency on several occasions since. Has had a backache for two years, and noticed that during a previous pregnancy that this symptom was slightly diminished. Present complaint: Dull aching pain in the dorsal region of the back, worse while doing housework. Has some discomfort in hips and feet, and, at times, in the lumbar region. Examination of the spine revealed entire stiffness of the dorsal portion, flexion, extension, and side bending being nil. There is slight enlargement of the left side of the heart, and a high grade of albuminuria. The treatment consisted in weekly use of the cautery, to the spine, followed by adhesive plaster strapping. She derived considerable benefit from our Zander machine for active spinal twisting, which somewhat resembles a revolving chair, whose motions are resisted by means of weights. The nephritic condition soon cleared up under appropriate medication. She is still under treatment, now principally centered on the machines and massage, and has been fitted with a spinal brace, to furnish support during the day.

Case IV.—Mrs. F. D., age 42, married, Russian. Referred for treatment of a long-standing backache, by the gynecological department of the Vanderbilt Clinic. The examination of the internal organs, it had been found, showed that there was a complete absence of the internal, and most of the external, organs of generation. She had never menstruated. In the lumbar region of the spine, she presented a fairly marked kyphoscoliosis, with the convexity to the left. The photograph does not indicate the size of this gibbosity as it should. There were numerous Heberden's nodes on the fingers, the hips seemed to be stiffened by a similar osteoarthritic process, and the entire picture pointed to a developmental defect in the pelvic organs, that had in some way been associated with a localized hypertrophic arthritis of the spinal column, at the same cord level. The recent history of this patient cannot be detailed, for I lost sight of her after measuring and fitting a spinal support.

591 Lexington Avenue.

A CASE OF HOOK-WORM INFECTION ENDEMIC IN NEW YORK.*

By HARLOW BROOKS, M.D.,

NEW YORK,

ASSISTANT PROFESSOR OF CLINICAL MEDICINE, UNIVERSITY AND BELLEVUE HOSPITAL MEDICAL COLLEGE, VISITING PHYSICIAN TO THE CITY HOSPITAL.

Hook-worm infection is a condition as yet uncommonly reported in New York City. Still more rarely are cases recorded in which the infection seems to have been acquired in our immediate vicinity. This has been a matter of surprise to those of us who are familiar with the prevalence of the disease in neighboring localities and who know of the considerable number of individuals who come to the city suffering from this parasite.

It is, however, highly probable that the infection will eventually become more generally disseminated here, especially from infected earth workers who have of late flocked to the city and its environs in large numbers to take part in the construction of our subways, water systems, and other operations involving extensive excavations. The danger of the spread of this infection under just such conditions as pertain here has been for a long time fully recognized in France, Switzerland, Italy, and other places, in some of which the climatic conditions differ but slightly from those of our city.

In so far as I am aware, no precautions to prevent the spread of this quite serious condition have been taken by the physicians in nominal medical control of these enterprises, and in some contracts I personally know that the hygienic and social conditions present in every way favor dissemination from known cases present. There are no cogent reasons why the infection may not become quite as serious a one with us here as it is in other localities, hence the importance of recognizing the first few cases of local infection which develop and the wide dissemination of knowledge concerning the disease. It is for these reasons that I desire to report the following case of local hook-worm infection which was discovered in my service at the City Hospital.

The patient was of Irish-American extraction, 55 years of age, and born in Philadelphia. He was well as a child, and the family and personal history have no bearing except for the fact that while a general laborer he had worked mostly at excavating, rock drilling, and the like. He had never in his life been further from New York than Pennsylvania, where he had worked for two years as a coal miner, during all which time he was perfectly well.

Two years before admission he was working as a rock driller in a reservoir at Brewster, N. Y. Several of his associates, including his immediate "helper," were Italians, some very recent arrivals in this country. Meanwhile he boarded at a farmhouse and lived very largely on milk. When he took this job he was in perfect health and of a ruddy complexion. He began, while engaged in this work, to suffer from headache and pains in the shoulders. About two months later he noticed that his legs began to swell, he became short of breath, and suffered greatly from dizziness, sometimes falling and losing his consciousness. He complained greatly of cardiac palpitation, and noticed that he had become very pale. He was obliged to give up work, and finally became so weak that he had to go to a hospital, where he remained from June until December. A diagnosis of pernicious anemia was made, but he finally improved sufficiently to permit his return home to Philadelphia, where he again entered a hospital, remaining there without improvement for six weeks. He finally returned to a New York hospital and was transferred to my service at the City Hospital with a transfer diagnosis of "pernicious anemia."

His chief complaints at this time were great weakness, dizziness, and palpitation with dyspnea. His appetite and digestion remained excellent. He was large and fairly well nourished. The skin was very pallid and of a pale yellow tint. He was mentally clear, and complained of no pain.

Examination of the chest presented nothing of note, and the heart sounds were found distinct and free from murmurs. The pulse was soft but regular, except after exertion, and ran from 72 to 88 per minute in the prone position. The abdomen was soft, somewhat retracted, and presented no points of tenderness. The splenic dullness could not be made out, and the liver border extended but to the free border of the ribs.

The temperature during his stay in the hospital

*Read before the Section on Medicine of the New York Academy of Medicine, December 21, 1909.

varied from 98° to 100° in the rectum. Examination of the urine showed a slight trace of albumin, but it was otherwise normal.

Examination of the blood showed hemoglobin, 25 per cent.; red corpuscles, 2,300,000 per cm.; leucocytes, 6,200; a few normoblasts and many poikilocytes, but no megaloblasts were found. There was great variation in the size of the erythrocytes and marked chromatic and endoglobular degeneration of the red cells. Differential leucocyte count showed the following significant finding: Polynuclear neutrophiles, 47.3 per cent.; small lymphocytes, 17.2 per cent.; large lymphocytes, 9.3 per cent.; mast cells, 1.8 per cent.; mononuclears, 3 per cent.; eosinophiles, 21.4 per cent.

Examination of the feces showed hook-worm ova in considerable numbers.

The patient was then given magnesium sulphate in purgative doses. The movements showed increased numbers of ova and an abundance of occult blood, but no parasites. Thymol was then administered in doses of 15 grains, followed by magnesium sulphate. At first no parasites were dislodged, but later a few appeared. The patient's condition had now become so serious that it was deemed wise to discontinue treatment for a week, during which time he was given a generous diet, chiefly of milk, eggs, and whiskey. Iron was given in the form of the tincture of chloride. The bowels were then again cleared by Epsom salts, food discontinued, and thymol given in doses of 30 grains daily. A considerable number of parasites and many eggs were discharged, but ova still persisted in the feces. After three days' rest the doses were repeated with the discharge of more parasites, but ova still were found in the movements. The patient was made quite seriously ill by the last doses of thymol, and as eggs still remained, after a rest of a few days beta naphthol was given in doses of 20 grains after the preliminary clearing of the gut by salts. This was followed by much less disturbance and by the discharge of many parasites in the feces. Less prostration followed this medication, which was repeated several times, and the patient's feces finally remained clear of ova.

Close examination of the parasite identified it positively as the European form of the worm, certainly differentiated from *Uncinaria Americana* by the position of the vagina, by the size, and by the arrangement of the buccal hooks.

The patient made a slow recovery under active ferruginous and dietetic treatment, but was not able to be discharged from the hospital for nearly three months. At this time the hemoglobin had reached 60 per cent. and the eosinophilic leucocytes had fallen to a relatively normal percentage. The general condition and feeling of the patient improved much faster than his hemic picture and he demanded his discharge, saying that he liked his job better than hospital treatment.

The interesting points presented by this case are, in brief, these: The infection was undoubtedly contracted in this State. As the identity of the parasite was definitely shown, it was clearly established that it was a European infection, probably received from his Italian associates.

The case demonstrates the well-known clinical resemblance between the anemia of uncinaria infection and pernicious anemia, and it strikingly demonstrates the necessity of examining the feces in all such instances. The diagnostic importance of the relative leucocyte count is also shown.

It is noteworthy that this patient passed through three hospitals, one of which was a well-known New York City institution, under a diagnosis of pernicious anemia, and he was sent to us in a presumably moribund condition.

The case also illustrates the difficulty with which this parasite is sometimes dislodged from the gut when it has remained there for a long time and it shows as well that treatment is not unattended with dangerous symptoms, even when thymol is given in inefficient though large doses. Beta naphthol in this particular instance appears to have acted better, though in two other cases under my observation thymol acted most satisfactorily and without the dangerous symptoms which attended its use in this instance.

In conclusion I wish to express my thanks to my house staff for their painstaking work and great interest in this case. My thanks in this respect are especially due to Dr. Snyder of the Sage Institute of Pathology who was at that time my house physician.

44 West Ninth Street.

LETTERS TO A NEUROLOGIST.

By JOSEPH COLLINS, M.D.,

NEW YORK.

PHYSICIAN TO THE NEW YORK NEUROLOGICAL INSTITUTE.

III.

"No love hath she, no understanding friend."

My dear Doctor:—I am very desirous of getting the facts of my case before you in the most telling way. It seems to me that I can do this best by sending you a letter which will contain the important points in my history, and then call upon you after you have had time to read it. To find oneself, thirty-six years old, alone, unattractive, unprovided for, and wholly incapable of earning a livelihood, is not a pleasant prospect, especially when ill-health is added to it. Many people think I am peculiar, but none of the peculiarities that I manifest are of my own choosing. I would gladly drop them and be like other people I see around me, who are evidently contented and happy.

The nervous exhaustion from which I suffer now began apparently in my twenty-first year, but I am convinced that it dates back to a humiliating and ignominous experience, a whipping given me by my father when I was nine years old. The thing that hurt me most was that my father, whom I worshiped, should be able to strike me. I am sure that the effect would not have been so lasting had I not had a great love for him and had not the whipping been done in anger. As a child, my affections were centered upon my father, an undemonstrative man, who used nothing less severe than criticism as a means of correction. This and the fact that he never gave outward token of affection or approbation, led me to believe, not only that he did not love me, but that he was displeased with me and disappointed that I existed at all.

This brought about a state of mind and feeling which not only made me very unhappy, but developed in me an attitude, a behavior, which led people to think me peculiar. I felt that if my own father was displeased with me and disappointed in me, others would certainly be so. I repressed myself in every conceivable way, and this included avoiding people. My father never sought to know his children. He never advised, encouraged or

praised. He either ordered or found fault. Criticism and correction were the tools he used in shaping his children's characters. No one knew my state of mind then, and I never spoke of it to anyone until many years later.

In my fifteenth year I began the study of painting and for five years I found in this work escape from myself and much happiness. But there was always a craving which I felt might be satisfied by someone who loved me, or perhaps even better by someone whom I could intensely love. Often in my despair of my father's ever understanding me or accepting my overtures of devotion, I would turn to companions of my own sex. Here also I was repulsed. Although some girl would be at first attracted by my admiration, she would very soon become listless and show signs of ennui when in my society and would shortly turn away from me, as though the very strength of my affection exhausted her. The fact of my demands being greatly in excess of her power to supply seemed to excite feelings of resentment and she would turn to more congenial and less exacting companions.

Is there no one in the world who cares to be deeply loved? Perhaps it is that only deep natures can bear to receive deep devotion and that the ordinary person under these circumstances merely feels disgust and resentment towards those who bring out superficiality which hitherto has been unsuspected. I cannot understand it at all, but I feel convinced that there is in me some force, which, denied a natural outlet, could still be utilized and made productive in some other direction, giving me a *raison d'être*.

In my nineteenth year I left home and went to study art. While there I experienced a remarkable change. I began to feel confidence in myself. When I returned home, and repressed myself no longer, I found people ready to admire and love me. Realizing that I was as capable and deserving of admiration as most of the girls of our acquaintance, I felt a bitterness toward my father which I had not before experienced. It is useless to dwell upon this now. I do not think that the hatred which would sometimes overwhelm me ever entirely supplanted my love for him, but it kept me in a state of bitter resentment. I could not understand how it was possible for him to tolerate himself and treat me, a part of himself, as he did. He was apparently unaware that any conflict was going on within me, or that I was unhappy. I made many plans to get away from home, to an atmosphere that would be favorable to spiritual growth and tranquillity, but I had no one to help me develop them, and it did not occur to any of my family that what they alternately considered as wilfulness, eccentricity, and misanthropy could be overcome by going away. Moreover, we were not so situated financially that I could ask to be sent to New York to study. Indeed, I am aware of the sacrifice that had already been made to send me to —— for the year.

My plans to get away were frustrated and my pangs of hunger for love were thwarted by a serious and protracted illness, a disorder of the intestines of a dysenteric nature, which attacked me at this time and which so utterly exhausted me that in two months I was scarcely able to move. For almost a year I was most miserable and listless, unable to do anything, and very nervous. When the symptoms of this disorder ceased I began to have headache and backache and entire cessation of a function, which alarmed me very much. I was now in such a state of apprehension that I thought I was losing my mind. I had never read or heard about nervous disease, and as I had indigestion constantly, I believed the trouble was with my stomach. The mental condition, I thought, was the result of being disliked and misunderstood.

I realized that I must get away. I knew my father would not consent to my coming to New York, so I did not discuss it with him. I told him I was going, and when he absented himself from home that day I did not even have an opportunity to say good-by to him. When my mother told him I had gone, his comment was that I had made my bed and could lie in it. I had got some money by selling several pictures, and I borrowed some from a clergyman.

The physician whom I consulted on my arrival here sent me to a nerve specialist, who said I was on the verge of nervous collapse and that I was already suffering from neurasthenia. He told me I should live an outdoor life in the country or go to a sanatorium. As I had just come from the country, and as I had no funds to pay for maintenance in a sanatorium, the only thing I gained from this consultation was the knowledge that I had a real disease. I tried to do some work, but inspiration and strength both failed me. For nearly two years I dragged out a miserable existence in hall bedrooms of "respectable" boarding houses in the vicinity of Stuyvesant Square.

Then I went home, fortified with all the good resolutions that I could command, and convinced that the trouble there must have been of my making or imagining. I was contrite and humble, filled with every desire for self-effacement. I wanted to go back and make my life harmonize with the life of my father. But my resolutions and my attitude did not long withstand the circumstances existing at home. It soon became very obvious that my father's peculiarities had become more accentuated. I shall never understand the injustice to his own children and his over-charitableness toward others. If a difficulty ever arose between his children and other children, he invariably took the ground that his children were in the wrong. Although he never did anything which could possibly contribute to make us what he wished us to be, he expected perfection from us, and was dissatisfied when he got it!

My parents are as dissimilar in temperament as it is possible for two persons of character and understanding to be. As for myself, I inherit those qualities of my father which my mother cannot understand and those of my mother which irritate my father. I appreciate my father's sterling qualities. I do not think that there exists a man who is his superior for uprightness of character and love of his fellow-men, so long as they are not his own flesh and blood. He is unusually broad-minded in many respects, and unusually narrow in others. He does not know the meaning of the word imagination, and he is apt to think that what he does not see or understand does not exist. My mother, who considers every one better than herself and never speaks of herself unless forced to, has had her personality effaced. In reality, she is a perfect mother so far as an automaton can discharge those duties. She believes that the queer streak in me is due to some experiences she had before I was born. At that time she had the care of her grandmother, who was very old and very ill. When my father would remain away from home until late at night this grandmother would insist that something had hap-

pened to him, and she would insist upon it to such purpose that my mother never failed to get apprehensive and frightened. When she spoke to my father about it and asked him to come home earlier, he said she was unreasonable and continued to remain away.

But whether or not my ill-health is due to some prenatal cause, I know that it exists, and that I must get over it. I have been in New York now for about five years, supporting myself in part by my own effort and in part through the bounty of friends. My only cheering thought is that I may get well and some day meet a man whom I will love and who will love me. I presume I ought to tell you that when I came back here some five years ago, utterly despondent and overwhelmed with loneliness, I met a man who awakened in me a force the existence of which I had up to that time been unwilling to recognize and too unhappy to realize. Quickly there developed something within me which made it impossible for me longer to dwell in the valley of despair. Happiness was in full sight, but although he liked me and found pleasure in my society, he did not love me. The strength of my own feeling so overmastered me that it forced me to believe, in spite of reason, that he must care for me. Within a year he married some one else.

Strangely enough, soon after I first knew this man I began to experience a decided change physically and mentally. For the past five years there has been a gradual return of strength, and now, save when I overdo, I am comparatively free from suffering. I cannot do any mental work, and my capacity for painting (what little I had, for I never overestimated my talent) has been entirely lost. I have to be extremely careful how I use my little fund of strength or energy, for if I am not always vigilant I suffer. When you see me, you will no doubt be astonished that my appearance does not betray my experience, but my appearance is not more deceptive than it is variable. When I am down I look it.

I am very easily excited and confused, and when tired I often use words incorrectly. Sometimes a fatigue overwhelms me which makes even thinking impossible until after I have slept. This mental helplessness is quickly induced by talking or by listening to what does not interest me. The nervous exhaustion that comes from overtaxing shows itself in emotionability, in painful pressure around the head, a pulling sensation extending from the eyes to the back of the head, in irritability, acute indigestion, and in a lot of other ways which I know you will understand.

I do not think I am what is called morbid, and I have not despaired of getting well, but when I think that the constructive and productive half of my life is gone, do you wonder that I feel disheartened and desolate? I am so eager to do anything that is within my power that words are inadequate to express my willingness. I am sad that Fate should have filled "Life's early cup with such a draught of woe," but I do not need consolation or encouragement. I need to get strong. I know how to extract the honey from the flower of life, if I can get the strength to stand up to it.

Believe me, with much respect, yours truly,

Dear Madam:—What is your desire, then? Is it to apprise me of your condition and state of mind, or is it to be told how to develop sufficient strength to justify you in setting out on your journey to the Hesperides?

You have given me an unusually clear and interesting account of yourself and of the genesis of your ego, and it is refreshing to get these from a patient instead of a catalogue of symptoms. Your statement that you do not need consolation or encouragement makes it easier also to answer your letter. We physicians spend so much of our time giving both that it becomes as natural to do it as it is to smile on meeting a friend.

An interpretation of your condition is not a difficult matter. Let us suppose that you are by nature a sensitive, impressionable, affectionate creature, that you have more of that indefinite quality called temperament than the average woman. The brutal incident that you relate as having occurred in your ninth year and the atmosphere of frigidity and unloveliness in which you spent the formative years of your life are sufficient to have eradicated, or at least dwarfed, every one of those qualities. Instead of this, the effect of your environment only caused you to throw around yourself a cloak of arrogance and self-sufficiency, in order that it might not be seen how nearly frozen to death you were. For a few years following the period of your physical maturation, your natural clamorings for emotional appeasement, your unconscious bids for affection, were allayed in a vicarious way by the appeal which color and painting made to you and by the physical labor of acquiring the capacity to use them.

The beating which you received, and upon which you lay such stress as a cause of your ill health and unhappiness, was probably a thorn in your emotional nature for a long time, but it had, I think, little or no relationship to your present condition. Moral or physical insults incurred at a time of life when it is impossible or inexpedient to resent them often, it is said, get stored up in the latent consciousness and act as a provocative agency of disease long after the memory has lost track of them. I do not think this is so in your case, particularly as it has withstood what we physicians speak of as the therapeutic test; that is, the attributed results of it have not disappeared after it has been brought up into consciousness and fully discussed. It is generally held that symptoms flowing out of such moral insults are most successfully overcome in this way. Such revival of latent memories, and the submission of them to careful analysis and logical inquiry, constitute an important feature of so-called psychotherapy, which one hears so much about nowadays. What this experience really did was to humiliate you and to convince you that you were neither loved nor appreciated. Instead of forgetting it, you hammered your iron when it was glowing hot, and you have gone on hammering it ever since.

If you had not been so unfortunate as to develop in your twentieth year the infectious disease you mention, it is probable that you would have entered young womanhood with sufficient physical strength and endurance to have frequently put you in the way of meeting that understanding friend whom you so badly needed. In reality, if you had married in your early maturity, and if with matrimony had come an average amount of felicity and "children with clamoring limbs and little hearts that err," you would not have got into the state in which you are now.

I venture to say to you, without inquiry as to whether or not you are a seeker for liberty in the

direction of suffrage, that woman is not a unit; she is only one-half a unit. She may be compared to a house the front of which is built and beautifully finished. Such structure is better than no house at all, but it lacks all the essentials of a comfortable dwelling-place. It needs a roof, it needs care, it needs direction in order to endow it with all the comforts that we expect in the home; and your sex, in order to develop those qualities which are essential to happiness, needs completion and direction. "Every wise woman buildeth her house."

There comes to every woman at the time of early maturity and coincident with it a functional capacity of certain cells or tissues of the body indicative of her growth and of her power to participate in that most wonderful and inexplicable of phenomena, creation. The secretion of these tissues is essential for the physical and moral development of the individual. Naturally, I am not saying to you that these cells cease to functionate if matrimony is denied the individual—it would be absurd to make such a statement—but with matrimony and its entailments come the completion of the human organism, it matters not what the sex of that organism may be. You may construe this as counsel to marry, and although I am unwilling to take it upon myself to advise you to marry without knowing more about you, I want you to know that it is the lack of adequate and satisfactory mating that I believe to be largely responsible for your condition.

It seems to me that you have a large endowment both of the instinct of family and of the social instinct as well. I should judge from your letter that you come honestly by the former, but the latter does not seem to me particularly evident in your father.

And now I wish to add a few words regarding your metal attitude and to counsel you as to the necessity of changing it. You have got yourself out of all perspective with life. It will require much determination and persistence on your part to get the world, or at least that part of it with which you come in contact, into the right focus again. You really have much to be thankful for. You are not hypochondriacal, and you are not a prey to obsession. You have not lost your will-power, and you still have confidence in yourself. You can readily see how much more difficult the situation would be for you if any of these conditions existed. But you take yourself too seriously. You center all thought on yourself, instead of projecting it in the direction of persons, things, and ideals. In my mail this morning I received a tiny booklet entitled "Thought Sickness." The writer, an earnest soul struggling with the problems of existence in a small town in North Carolina, thinks he has discovered the "law" that "governs" the relation of thought to disease, in the same way that Newton discovered the law of gravitation. His "law of cure" is: "Thought or attention to, increases pain and hinders Nature's efforts to cure. When the entire thought output is engaged with something other than self, the natural powers of Nature to cure are exercised to their greatest extent." He has made a discovery that countless millions have made before. Possibly you haven't made it yet? You should set about it, and while so engaged keep a watchful eye out for limitations.

When you combine the rare gift of a just appreciation of your own limitations with a certain knowledge of your sex and its functional destiny, you will, I think, take the first determining step along the road that leads to the goal of health. The individual comes into this world with certain endowments: not alone physical, but also emotional, spiritual, temperamental—call it what you will. His physical endowment permits him to grow to a certain height, which he can neither dwarf nor exceed by effort of his own. He can facilitate and possibly expedite his growth, and he can impair the degree of completeness or perfection to which he is entitled, but he cannot fundamentally increase or diminish the height with which he is endowed. You have an emotional or temperamental endowment which clashed with that of your family, and particularly your father. He either had no capacity to understand a nature such as yours or he had no inclination to attempt to interpret it; therefore he was neither sympathetic to you when you were ill nor appreciative of your spiritual and emotional needs when you were well.

The longer you dwell upon your troubles, the more difficulty you will have in overcoming them. Forget the incident of your youth which seems to you so important. Try to live in the future, not in the past. Cease rehearsing your disagreeable experiences and refrain from dwelling on what you think are their inevitable results. The experience that you had five years ago is an indication that your physical and mental health will find prompt restoration if the opportunity comes to you to fulfil your physiological destiny. In the meantime, "assume a virtue if you have it not," and in proportion as you are able to live your life for others, so will the opportunity be offered you to find your destiny.

Defective vision is said by Taussig of St. Louis to be slightly more common among school girls than boys, and defective hearing more common among the boys. The difference is slight.

Etiology and Pathology of Noninfectious Melena of the Newborn.—A. Bonnet-Laborderie gives us a study of the etiology and pathology of melena of noninfectious origin in the newborn, with an account of a typical case. The diagnosis between the infectious and noninfectious forms is based on the early appearance, curability, localization of hemorrhage in only one organ, the intestine, and the general good condition of the child in the noninfectious form; as contrasted with a late appearance, bad general condition, many sources of hemorrhage, and fatality of the microbian form. The localization of hemorrhage in the intestine depends on the liability of the intestinal mucosa to congestion at birth, with hypertrophy of the spleen and liver, and a sudden abolition of the uteroplacental circulation. After considering the various theories advanced to account for these hemorrhages the author states that he believes them to be due to difficulty of establishing respiration at birth, which causes an increased blood pressure, resulting in extravasations and ulcerations in the stomach and intestines.—*Journal des Sciences Médicales de Lille.*

The Rapid Development of Tumors During Pregnancy.—Michele Monforte describes two cases of tumor observed by himself, in which there was a rapid increase during pregnancy and a diminution in size as soon as labor was over, and gives the histories of three other cases recorded in literature. As to the cause of this increase during pregnancy he analyzed the possible causes of the changes observed. During pregnancy there is a change in the composition of the blood and in its quantity, and an increase of vascular tension, with an increase in the size of the heart. There is a congestion of the abdominal organs, an autointoxication, and influences due to the neurovascular mechanism which have something to do with the increase in size of tumors. A hyperproduction of nutritive elements and of toxic substances takes place, and it is possible that these toxic materials stimulate the cells at the point of the tumor formation and cause a rapid increase of cell formation. The suppression of the menstrual function is a cause of congestion during pregnancy. This removes one of the chief eliminative functions of the female organism. When labor has taken place the hemorrhage, decrease of vascular pressure, slowing of the pulse, and elimination of toxic products causes a regressive action in the tumor cells and a diminution in size. —*Annali di Ostetricia e Ginecologia.*

New York, January 29, 1910.

THE EPIDEMIOLOGY OF TYPHOID FEVER.

A FEW years ago the question of the mode of spreading of typhoid fever was considered to be settled, and the prevalence of an epidemic of the disease in a community was taken as *prima facie* evidence of a contaminated water supply. The result of this belief was a widespread reform in the methods of supplying our cities with water. Watersheds were investigated, cleaned up, and policed; filtration plants were installed for our rivers; and new intake tunnels were built into our lakes. The result of this movement was indeed striking, and in some instances, notably in Philadelphia and Cleveland, where the cases of typhoid fever had been numbered by the thousands, within a few weeks they become comparative rarities. It was, however, soon learned that while pure water greatly reduced the amount of typhoid fever in a community, it did not entirely eradicate the disease, local epidemics and sporadic cases continuing to crop up here and there even when the water supply was apparently above reproach.

Attention was then turned to sources of contagion other than water. Oysters and other shellfish taken from polluted waters and eaten raw were considered to be responsible in some instances. Impure milk was held up as a source of danger, and many local epidemics were traced definitely to such sources. The house fly came in for a goodly share of attention, and by many has come to be considered the chief source of contagion, particularly in smaller towns and rural districts, where the more primitive type of toilet facilities makes the contamination of the fly with human excreta a simple matter. Within the last two or three years attention has also been turned to the danger of "typhoid carriers." The discovery, however, that typhoid fever may on occasion be conveyed by any one means is far from proving that it is of necessity so carried in all instances, and in every city are found many cases which do not seem to be explicable on any one theory. Washington furnishes an example of a city which has suffered recently from a particularly widespread epidemic, or better endemic, of typhoid fever of obscure origin. Here, in spite of a good water supply and a vigorous sanitary campaign, the mortality rate from the disease, though in no way comparable with that of some of the large cities a few years ago, is among the highest in the country.

The cause of this continuing epidemic of typhoid fever in Washington has been investigated by the Public Health and Marine-Hospital Service, its third report upon the subject having been published recently in the Hygienic Laboratory Bulletin, No. 52. This report covers the studies made by Rosenau, Lumsden, and Kastle into the typhoid situation in the District of Columbia during the year 1908. The work was extensive, covering all cases which could be discovered in the city, and intensive, many blocks of houses being investigated minutely, as to every inhabitant, either sick or well. The results of this painstaking work are possibly to a certain extent disappointing, no one factor being at all definitely proven as the chief cause of the epidemic. A few points are, however, well worthy of mention. The water supply was found not to be responsible for much, if for any, of the disease. By a careful comparison of the prevalence of flies and the cases of typhoid fever, no relation could be determined between the fly curve and the fever curve. Milk was shown to be the source of contagion in several localized epidemics, in one of them the infection having been traced back from two dairies to one farm, whose owner, though in good health, was found to be a "typhoid carrier." Quarantining this farm promptly checked the spread of the epidemic. Personal contact with ill patients was found to be a matter of more importance than it is generally considered to be, and is stated by the investigations to be "one of the major factors in the spread of the disease."

The points, however, in these investigations which seem to be of especial interest, pertain to the subject of "typhoid carriers." Not only did the well-known form of chronic carrier occur, in whom the bacilli remained active for months or years after attacks of the disease, but harborers of the germs were found who gave no history whatever of previous attacks. Some of these, after having carried the germs for long periods without the appearance of symptoms, finally, owing to lowered resistance or some other cause, themselves succumbed to the disease. Still another type of carrier was that in which the organisms were found on examination of the excreta of healthy individuals at one inspection, whereas a few weeks later they were again looked for in vain. These temporary carriers, if they prove to be as common as the present studies would suggest, three such instances having been found in the examination of one thousand healthy persons, may prove to be factors of some considerable importance in the spread of the disease. They would certainly suggest the possibility of contagion by means of a third party himself immune.

CALCIUM AND ECLAMPSIA.

SOME experiments undertaken by W. Blair Bell and Pantland Hicks on the physiology of the female genital organs, described in the *British Medical Journal*, Feb. 27, 1909, have incited A. C. F. Halford of Brisbane to write on the subject of calcium metabolism in the *Australian Medical Gazette*, Nov. 20, 1909. Halford notes that the chief results from the investigations described in our London

contemporary prove that the phenomenon of menstruation bears a close relationship to the calcium content of the blood. Menstrual discharge is found to be very richly charged with calcium, and this excretion coincides with a marked fall in the calcium content of the blood. Further, when a woman becomes pregnant such excretion of calcium necessarily stops and the question arises, how is it employed in the pregnant state. The needs of the embryo in the earlier months will be but small, so that for a few months the mother's calcium content must continue high. In the later months, however, the fetus will draw largely on the calcium salts in the mother's blood for the building up of the skeletal structures, and it is when this demand reaches its height, in the seventh month and after, that symptoms of the preeclamptic stage occur.

According to Halford, the symptoms of low calcium content are identical in many ways with eclamptic phenomena. The most prevailing are edema of the extremities and loose cellular tissues, and convulsions. An exclusive milk dietary is a part of the treatment of this condition, and milk is rich in calcium. After labor calcium will again accumulate in the blood, but it takes three days to rise sufficiently to stimulate excretion by the mammary glands, and the function or site of calcium excretion being now transferred from the uterus to the breasts, the catamenial discharge remains in abeyance while lactation lasts. In short, the theory propounded is that eclamptic symptoms and eclampsia are due to the absence or comparative absence or lack of sufficient calcium in the blood, and conversely that it is essential to the pregnant woman in order to be free from eclampsia and from hemorrhage that the calcium content of the blood continue high.

Halford's treatment for exclampsia and eclamptic symptoms, as well as for the albuminuria of pregnancy, which, in his opinion, may be also due to paucity of calcium content of the blood, is by the administration of calcium salts in generous doses. He has treated a few cases in this manner with encouraging results, or rather it should be said, he thinks he has averted eclampsia by following this procedure. Lactate of calcium has been the form employed both on account of its ready assimilable nature and because it is an organic compound. The dosage was 15 grains every four hours until symptoms abated and then less frequently. The theory advanced by Halford and others reads as if it were based on sound premises. His experience in practice seems to have been satisfactory, and if a wider use of calcium in the treatment of eclampsia is attended with beneficial results, a therapeutic remedy of very considerable value will have been unearthed. It may be stated that in dangerous cases of eclamptic convulsions the author recognizes that to give calcium by the mouth would be too slow a method, and in such cases he recommends the injection intravenously of a liter of warm saline solution containing about ten grains of calcium lactate.

Legal Rights and Tuberculosis.

At the Seventh International Tuberculosis Conference at Philadelphia, September 25, 1908, Samuel G. Dixon read a paper on legal rights and tuberculosis in which the trend of medical opinion is clearly shown. The difficulties in the way of successfully combating tuberculosis have presented themselves recently in various forms, and the only mode of overcoming these obstacles is to prove to the public that pulmonary tuberculosis is a disease which under certain conditions is easily disseminated and to make plain the methods whereby its dangers can be limited or even wholly eradicated. The ordinary individual is not alarmed by the presence of consumption as he is by the outbreak of a violent epidemic of smallpox, typhoid fever, or other infectious and contagious diseases. Consumption does not vividly impress itself upon his comprehension and consciousness as do these maladies and therefore he is apt to be lethargic in regard to its potency as a public menace. Its insidious nature robs it of much of its terror. However, to those who understand tuberculosis from bacteriological and clinical standpoints, it is a far more dangerous disease than the classical epidemic diseases, and it is its very insidiousness that renders it so. Dixon defines the legal rights of the people as comprised in the single word protection—protection to life, to health, and to property—and draws attention to the fact that by an unfortunate twist in the mental conception of our people there are a hundred laws for the protection of property to one for the protection of life and health. Consequently he thinks that it should be our first business as sanitarians to correct this mental obliquity and to enable the public to see things in their correct relations, and he tabulates eleven aphorisms with this end in view. Space is lacking here to refer in detail to these. Indeed, they are obvious to the medical man, and have even been brought to the notice of the layman many times during recent years. Nevertheless it is only by constant recapitulation that the masses can be made to appreciate that if they thoroughly understood what their legal rights are and insisted upon their enforcement, a very long stride would have been made in the direction of staying the spread of consumption. For instance, people have an undoubted right to pure milk, but, as a rule, they do not obtain it. In some cities, New York among them, strong efforts are being put forth to procure a pure milk, but in the majority of towns and in the rural districts generally, a deplorable apathy is manifested on this point. Again the people have a right to demand pure water, but in this case also they are frequently denied this right. Wherever possible consumptives should be segregated, and invariably they should be isolated in public institutions. In the new central prison about to be erected in Ontario a separate wing is to be built for the accommodation of those afflicted with tuberculosis, a departure deserving of the highest commendation. If medical men will but continue to educate the public in regard to the danger of consumption and drive home the fact that the people have certain legal rights which should be insisted upon, the disease must gradually disappear.

Contagion in Hospitals for Children.

In times of epidemics of measles, scarlet fever, and other contagious diseases, the general hospitals for children which for a time may be exempt, sooner or later receive some children who are supposed to be suffering from non-contagious disease, but who are in the incubative period of a contagious affection. These are usually isolated only after the in-

fection has already spread among the occupants of the ward. Periodically after that, at the end of the incubation period of the disease, another and another case appears indefinitely, until it becomes necessary to close the ward for disinfection. Such a disease as measles, which in the home seems to be a simple, benign disease, becomes a serious affection in a hospital where are congregated children already sick with other diseases or who have been operated on, as is shown by its considerable mortality. Scarlatina is still more serious and contagious. Influenza and bronchopneumonia spread as rapidly in children's hospitals and result as fatally. P. Chatin, writing in the *Lyon Médical*, for December 5, 1909, gives his experience in this respect in his service at the Hôpital Charité at Lyons, where he had a service for boys and a ward for infants. Measles got into his wards and at the end of about nineteen days, time after time a new case of measles appeared, until the ward was closed for disinfection. He suggests as a practical measure to prevent such an occurrence the division of one ward into separate compartments with glass partitions reaching a part of the way to the ceiling, but allowing of a circulation of air above the partitions. Every child who enters the hospital is placed in one of these compartments and cared for there until the period of incubation of the contagious diseases is over, that is for about three weeks. In hospitals where this has been done it has proved an effectual means of preventing the bringing in of contagion from without.

News of the Week.

New York State Committee for the Red Cross Society.—The American Red Cross has formed a New York State board, to consist of Governor Hughes as president, Cleveland H. Dodge, Jacob H. Schiff, Mrs. W. K. Draper, George C. Boldt, Robert W. De Forest of New York, Robert C. Pruyn of Albany, Colonel William Cary Sanger of Sangerfield, Alfred T. White of Brooklyn, and Ansley Wilcox of Buffalo. This board is to serve as a standing finance committee for the American Red Cross in the State of New York. Its function is to become the custodian of contributions given for relief purposes by the people of the State, in response to appeals from the Governor or from the Red Cross, in the event of the occurrence of a great disaster. Jacob H. Schiff has been appointed treasurer of the board.

Metropolitan Sanatorium Allowed.—The State Insurance Department has announced that approval has been given by it to the proposal of the Metropolitan Insurance Company to purchase 250 acres of land in Westchester county for the purpose of erecting and operating a sanatorium for the treatment of tuberculosis among its employees.

The Letchworth Village Commission, in retiring after completing their work of organization, passed a resolution expressing their thanks to the State authorities and all others who had aided in the formation of the institution. The work will be now carried on by the following board of managers appointed by Governor Hughes: *Chairman*, Mr. Frank A. Vanderlip; *Secretary*, Mr. Franklin B. Kirkbride (37 Madison Avenue, N. Y.); *Treasurer*, Mr. Leopold Sondheim; L. Pierce Clark, M.D.; Mr. Thomas J. Colton, Miss Casisty E. Mason, Miss Marion R. Taber.

Pollution of State Waters.—Attorney-General O'Malley of New York has rendered an opinion to the State Commissioner of Health in reference to the law regarding sewers emptying into State waters. The provisions of the public health law enacted in 1903 prohibit the discharging of sewers into any waters of the State except on express permission by the State Commissioner of Health. Commissioner Porter has advised the Attorney-General that this law is being violated by a great many municipalities throughout the State and asked the Attorney-General for an interpretation of the expression "waters of the State" as used in the statute. Attorney-General O'Malley holds that this refers to all tidal waters and all lakes and streams which are openly and notoriously used for navigation and also to any other waters which are in fact navigable or dedicated to public use for navigation or for a highway. The Attorney-General points out that the statute specifically provides that suits to restrain violations of this law or for the penalties prescribed are to be brought by the local boards of health.

Molluscum Contagiosum at the University of Pennsylvania.—About 150 students in the University of Pennsylvania have been attacked by molluscum contagiosum acquired it is believed through the gymnasium swimming pool.

Scarlet Fever and Measles in Buffalo.—A severe epidemic of scarlet fever and measles is prevailing in Buffalo. The situation is especially serious because the Common Council is at present deadlocked on the question of a site for a contagious disease hospital.

Measles in Brownsville.—The Brownsville section of Brooklyn, the seat of most of the poliomyelitis cases in Greater New York last summer, is at present having an epidemic of measles. During the first three weeks of January 1,067 cases were reported to the Board of Health.

Compulsory Treatment of Consumptives.—Secretary Probst of the State Board of Health of Ohio has prepared a bill which he will present to the present Legislature making treatment for tuberculosis compulsory and giving health officers power to order the imprisonment of refractory patients. The health officer is to have authority to enter homes where there are consumptives and put them in sanitary condition, and to send patients to hospitals for treatment.

Dr. Joseph S. Evans, instructor in medicine in the University of Pennsylvania, has been elected professor of clinical medicine in the University of Wisconsin.

A Department of Experimental Biology has been created by the Board of Directors of the Rockefeller Institute for Medical Research. Prof. Jacques Loeb of the University of California has been appointed as its head. He will assume charge of the department on July 1 next.

Lectures on Prevention of Disease.—A series of lectures on prevention of disease is to be given at the New York Academy of Medicine, 17 West Forty-third Street, under the joint auspices of the Public Health Education Committee of the Medical Society of the County of New York and the Hygiene Committee of the New York City Federation of Women's Clubs, on Thursdays, from January 20 to April 7, 1910, at 3.30 P.M.

Amalgamation of Medical Schools in Richmond.—At a special meeting of the faculty of the

Medical College of Virginia, held January 8, 1910, a proposition was made by Dr. Stuart McGuire, President of the University College of Medicine, that the two institutions unite and the proposition was accepted. It is understood that the entire faculties of both colleges will resign and a new one be appointed by a joint committee. No time has been set for the change as the action of the faculties must be ratified by the boards of trustees. The action was precipitated by the recent burning of the buildings of the University College of Medicine.

Phipps Institute for the Study, Prevention, and Treatment of Tuberculosis.—Drs. Charles H. Frazier, John H. Musser, David L. Edsall, and A. C. Abbott have been appointed by Provost Harrison of the University of Pennsylvania managers of the Phipps Institute for the purpose of entering upon the construction of the new building with the money contributed by Mr. Phipps.

Temple University, Philadelphia.—Dr. C. E de M. Sajous has been elected professor of therapeutics, materia medica, and pharmacology, Dr. J. F. Schamberg professor of dermatology and physiology, Dr. J. H. McKee professor of pediatrics, Dr. S. D. Ingham clinical professor of neurology, Drs. G. Morton Illman and Rae S. Dorsett associate professors of medicine.

The University of Michigan Medical Department.—The Board of Regents of the University of Michigan has adopted resolutions and appointed a committee to look into the desirability of removing the senior year students in the medical department to Detroit. It is suggested that this may result in the union of the Detroit Medical College with the University of Michigan.

Charitable Bequests.—By the will of Mr. John Stemme of New York, who died on January 10, German charities in New York will benefit to the extent of $80,000. Mr. Stemme left $10,000 to the German Hospital and Dispensary, and $5,000 each to the Wartburg Home for the Aged and Infirm in East New York, St. Mark's Hospital, St. Francis's Hospital, Montefiore Home for Chronic Invalids, Mount Sinai Hospital, German Poliklinik of New York, the Isabella Home, the German Hospital Society in Brooklyn, and the Fritz Reuter Home for the Aged at Union Hill, N. J. By the will of the late Matthew Corr of Philadelphia the following bequests are made: St. Joseph's Orphan Asylum, $10,000; St. Joseph's Hospital, for the endowment of a free bed in the name of the testator, $5,000; St. Mary's Hospital, for the endowment of a free bed in the name of a nephew, Bernard J. Corr, $5,000; St. Agnes Hospital, for the endowment of a free bed in the name of a sister-in-law, Catherine Corr, $5,000; Philadelphia Protectory for Boys, $10,000. By the will of the late Anna A. Porter of Philadelphia the sum of $10,000 is bequeathed to the Methodist Episcopal Hospital. The German Hospital of New York has received a gift of $100,000 from Mrs. Anna Woerishoffer of New York on the condition that a division for the diseases of children be formed to be known as the "Dr. Abraham Jacobi Children's Division."

The Metropolitan Life Insurance Company has received a gift of ninety acres of land and $100,000 for the foundation of its proposed tuberculosis sanatorium. The name of the donor is not made public.

Montefiore Home's New Site.—A new site for the Montefiore Home has been procured in the West Bronx section of New York City, between Columbia Oval and the Williamsbridge reservoir. A plot of about fourteen acres has been purchased by the committee appointed a short time ago to make arrangements for new quarters.

Clinic of the Harvard Medical School.—The free clinic to be run in connection with the Harvard Medical School in its new buildings in the Fenway, in Boston, was opened on January 10, 1910. The clinic is under the supervising charge of Dr. H. P. Howard, Dr. Henry A. Christian, and Dr. David Cheever.

The Portland (Ore.) Free Dispensary was opened on January 7, 1910. It is connected with the University of Oregon.

New Clinic for Jacksonville.—At a meeting held in Jacksonville, Fla., on January 10, 1910, a society was formed for the purpose of organizing a new eye, ear, and throat clinic in that city. Mr. George L. Drew was elected president, and Dr. F. P. Hoover, secretary.

The Rhode Island Anti-Tuberculosis Association is putting forth its principal effort in behalf of a hospital or hospitals for the treatment of advanced cases of tuberculosis. At the present time there are somewhat over 1,000 deaths a year from tuberculosis and facilities for the care of only 120 advanced cases.

The New York Physicians' Mutual Aid Association.—At the forty-first annual meeting of this association, held at the New York Academy of Medicine on the 18th inst., the president's report stated that there were nearly 2,000 members and a principal fund of over $70,000. The following officers were elected for the current year: *President,* Dr. W. F. Mittendorf; *Vice-Presidents,* Drs. Wendell C. Phillips and J. W. Ingalls; *Secretaries,* Drs. A. Edward Davis and Edward S. Peck; *Corresponding Secretary,* Dr. W. B. Jennings; *Treasurer,* Dr. Daniel Lewis; *Trustees,* Drs. Samuel Lloyd, W. B. Hoag, Heinrich Stern, C. E. Bruce, and D. P. Austin.

The North-Western Medical and Surgical Society of New York City, at its annual meeting, elected officers as follows: *President,* Dr. Godfrey R. Pisek; *Vice-President,* Dr. Linnæus E. La Fetra; *Secretary,* Dr. T. Homer Coffen; *Treasurer,* Dr. Henry L. Taylor.

Obituary Notes.—Dr. James H. Richardson of Toronto, Canada, died at his home, January 15, 1910, aged 87 years. Dr. Richardson was the first graduate in medicine of the Toronto University, having received his degree in 1844 from the Toronto School of Medicine, which afterwards was merged into the University. After serving in Guy's Hospital, in London, he returned to Toronto and became professor of anatomy in the University in 1850, a position which he held either in the Toronto School of Medicine or the University of Toronto until 1902, when he became emeritus professor of anatomy. He was for many years surgeon major of the Tenth Royal Grenadiers and of the Queen's Own Rifles. He was appointed on the consulting staff of the Toronto General Hospital at its opening, in 1854, and was the last survivor of the original staff.

Dr. W. Frank Haehnlen of Philadelphia died on January 15, 1910, at the age of 50 years. He was graduated from the University of Pennsylvania with the degrees Ph.D. and M.D. in the year 1882, and he served as resident physician in the Philadel-

phia Hospital in 1882-83. After studying abroad he became lecturer on obstetrics in the University of Pennsylvania. He was gynecologist to the Philadelphia Hospital and at one time physician-in-chief and gynecologist to the Samaritan Hospital. For the past fourteen years he had been professor of obstetrics in the Medico-Chirurgical College and obstetrician to the Maternity Department of the Medico-Chirurgical Hospital. He was a member of the Philadelphia County Medical Society, the Medical Society of the State of Pennsylvania, the American Medical Association, and the Philadelphia Obstetrical Society.

Dr. Joseph H. Chandler died at Wilmington, Del., on January 15, at the age of 70 years. He was graduated from Jefferson Medical College in the class of 1870. He was the oldest practitioner in the State of Delaware.

Dr. Daniel I. Avery of Lebanon, Mo., died at the home of his brother in White Hall, January 1, 1910. He was a graduate of the Rush Medical College in 1879.

Dr. Dwight Ruben Bement of Mount Ayr, Ia., died suddenly of heart disease on January 10, 1910, aged 70 years. He was a graduate of the Eclectic Medical Institute of Cincinnati, in 1878, and a veteran of the Civil War.

Dr. William Symington Brown of Stonham, Mass., died at his home, January 6, 1910, aged 88 years. He was a graduate of the University of Pennsylvania, in 1855, and was a member of the Middlesex County and Massachusetts Medical Societies. Dr. Brown during the Civil War was assistant surgeon in the Thirty-third, and surgeon in the Fifty-fifth Massachusetts regiments.

Dr. Homson White Cole of Danville, Va., died at his home, January 8, 1910, aged 79 years. He was a graduate of the Jefferson Medical College in 1854, and a member of the Danville Academy of Medicine and the Medical Society of Virginia. He was a veteran of the Confederate army, and for three terms Mayor of Danville.

Dr. Otto Fikenscher of Sibley, Ill., died at Lebanon, Mo., January 6, 1910, aged 37 years. He was a graduate of the Barnes Medical College of St. Louis, in 1897.

Dr. J. H. Gunning of Oakland, Cal., died at his home, January 4, 1910, aged 67 years. Dr. Gunning was a graduate of the New York University and for many years was on the faculty of that institution as professor of anatomy. During the Civil War Dr. Gunning served in the medical corps of the United States Navy.

Dr. William Clary of Bellbuckle, Tenn, died at his home, January 9, 1910, aged 79 years. He was a graduate of the Vermont Academy of Medicine, in 1855, and was a member of the Bedford County Medical Society and the Tennessee State Medical Association.

Dr. J. D. Pryor of Mayfield, Ky., died at the Riverside Hospital, in Paducah, January 7, 1910. He was a graduate of the University of Louisville, in 1890, and was a member and former president of the Groves County Medical Society and the Kentucky State Medical Association.

Dr. Daniel S. Richards of Richmond, Me., died at his home, January 7, 1910, aged 82 years. He was a graduate of the Bowdoin Medical School in 1856.

Dr. John P. Wilson of Poughkeepsie, N. Y., died at his home, January 16, 1910. He was a graduate of the College of Physicians of New York in 1870. For twenty-one years he was Assistant Surgeon of the Twenty-first Regiment N. G. S. N. Y.

Dr. John J. Sherman of Marinette, Wis., died suddenly, at his home, on January 9, 1910, aged 80 years. He was a former Mayor of Marinette.

Dr. Stewart Church of Brooklyn, N. Y., died January 16, 1910, aged 63 years. He was a graduate of the College of Physicians and Surgeons in 1870. He was a member of the Kings County Medical Society and the Medical Society of the State of New York.

Dr. David W. Coon of Trenton, Mo., died at his home, January 10, 1910, aged 55 years. He was a graduate of medicine in 1891, and was a member of the Grundy County Medical Society, the Missouri State Medical Association, and the American Medical Association.

Dr. John Hanson Wheeler of Louisville, Ky., died January 8, 1910, aged 84 years. He was a graduate of the Transylvania University, in Louisville, and a veteran of the Mexican War.

Dr. Joseph V. Latourneau of Laconia, N. H., died at his home, January 13, 1910, aged 48 years. He was a graduate of the Medical Department of Laval University, in Montreal, in 1889.

Dr. Albert Reed Barrett of Philadelphia died at Scranton, Pa., on January 18, at the age of 69 years, as the result of an operation performed for the relief of an affection of the stomach acquired during the Civil War. During the war he served with the Fifth New York Volunteers and with Rerdan's sharpshooters. Later he became a bank clerk, studying medicine during the evenings, and he was graduated from the medical department of the University of Nashville in the class of 1877. Somewhat later he became a bank examiner for the Government and more recently he has acted as expert accountant.

Dr. Joseph A. McFerran died at Laurel, Del., on January 8, at the age of 83 years. He was graduated from Jefferson Medical College in the Class of 1847. He practised his profession for many years in the city of Philadelphia and he was Visiting Physician to the Philadelphia Hospital from 1880 to 1884.

OUR LONDON LETTER.

(From Our Regular Correspondent.)

SLEEPING SICKNESS—PNEUMONIA AND POINTS IN ITS CLINICAL HISTORY—HYSTERECTOMY—FIBROID FROM GÄRTNER'S DUCT—OBITUARY.

London, January 7, 1910.

The report of Sir Hesketh Bell on the measures taken for dealing with sleeping sickness in Uganda testifies to the "courage bordering on heroism" of those engaged in the investigation of the disease. It has to admit that no discovery of therapeutic value has been made; all that can be claimed is that drugs have reduced suffering and perhaps prolonged lives. It is believed that for the last three years no European resident has taken the disease, but the mortality among the natives is terrible. In 1900 there were 8,430 deaths; in 1903 no less than 30,441. During six years an aggregate of 92,544 has been reached in the Kingdom of Uganda alone. In Busoga, where statistics are not available, the mortality is probably quite as high. If Unyoro and the Nile district were to be included, it might be taken that the total mortality in the Uganda Protectorate to the end of 1906 considerably exceeded 200,000. So long as means are taken to maintain a rigid *tabu* of all fly infested districts no risk of recrudescence is anticipated. During 1907 the deaths

were about 5,000; during 1908 only 3,662. For the first six months of 1909 only 459 deaths from the disease took place in the Kingdom of Uganda.

The most important administrative measures are stated to be the removal of the inhabitants from areas infested by the tsetse fly and the establishment of segregation camps, where those infected may live under medical supervision. Owing to the exuberance of the vegetation the clearance of infected districts is very costly, but it has been found that the planting of citronella grass has been efficient in keeping down the rank undergrowths, as well as in driving away several kinds of noxious insects. The researches of Sir D. Bruce and Dr. Kleine are mentioned as the most important recent contributions to our knowledge of the disease, showing the means of infection of the tsetse, that it cannot transmit the disease until after seventeen days, but probably retains its infectivity for two years.

At the Polyclinic Dr. Percy Kidd gave an exceedingly interesting lecture on some of the points in the clinical history of pneumonia. The subject is large enough and in a sense it is familiar, but it may also be said that so many differences and even peculiarities are met with in its course that the careful practitioner is often temporarily nonplussed. Even the lecturer, with his extensive experience as physician to the London Hospital, mentioned points which he had observed but rarely. He referred only to the lobar form due to the invasion of the pneumococcus. The relation to influenza he held to be that it prepared the soil for the microbe, and the tendency to diagnose a combination of the two diseases is a mistake, the pneumonia being usually, if not always, the only infection.

This error is very likely to occur when the physical signs set in late, say on the fourth day, or even the fifth, which may happen, and then it is thought that the pneumonia has supervened on influenza, especially should the latter be epidemic at the time. This may be the sequence of events in some cases, but Dr. Kidd thinks less frequently than many suppose. Pneumonia may certainly follow influenza and is a grave complication, often attributed to getting up too soon; but the difficulty of diagnosis and prognosis lies in the insidious onset and late development of physical signs in certain cases, and these cases are not particularly rare, but a large proportion have been erroneously called "influenzal pneumonia."

Though severe rigors are mostly supposed to warn us of a severe infection, this is not a rule, and Dr. Kidd related several examples—one a striking one in which four severe rigors ushered in pneumonia of the right lower lobe in a man of 27 and the disease ended in crisis thirty-six hours later.

Abdominal pain is known as a mode of invasion, mostly in children, sometimes in adults, as in a case admitted to the London Hospital in a boy of 16 for pain and tenderness in the right iliac fossa and therefore at first placed in the surgical wards, but transferred to Dr. Kidd's care when the surgeons found absence of rigidity of the abdominal wall. There was consolidation of both lobes of the right side and favorable issue occurred by crisis on the twelfth day.

Among rare onsets symptoms of meningitis are apt to mislead, but such cases are not uncommon in children.

Hemoptysis is a very rare initial symptom—that is, free hemorrage, not the well-known scanty, stained expectoration. The lecturer then touched on the irregularities of the fever and then referred briefly to physical signs. On these there is one point I should like to give, viz., that in resolving cases crepitus redux is oftener absent than present. Now, as resolution is effected by absorption of the liquefied alveolar exudation, we might expect to hear it, and the fact that we so often do not throws doubt on the alveolar origin and suggests that crepitus redux and crepitant râle are really produced in the small bronchi.

Complications were considered by the lecturer as expressions of a secondary infection, and in other cases the pneumonia itself as secondary. True mixed infections are very rare. When bronchitis complicates the case a prolonged course and defervescence by lysis may be expected. Laryngitis is not a frequent complication. Albuminuria, delirium, diarrhea, and embolism were mentioned and cases briefly related.

Further, as to what appear mixed infections, Dr. Kidd had more than once observed lobar pneumonia coming on during the course of typhoid, but in only a single case, which he related, had he met with it at the very start. He related another in which it seemed probable that there was a combination of rheumatic fever and pneumonia.

Relapsing pneumonia is rare if we restrict the term to complete suspension of pyrexia with resolution and afterwards a reappearance of early symptoms and repetition of the process. Such a case is one of reinfection—probably from some focus in the lung.

Delayed resolution sometimes occurs, but exploratory puncture mostly reveals fluid as the cause of the prolonged dullness. If not, patients should leave the bed and move about a little.

Fibrosis has been much discussed. Some are febrile and progress to a fatal termination. Cavities may be formed and foul sputum result. In other cases fibrosis may take place very insidiously, apparently arising out of delayed resolution, without fever or constitutional disturbance, and the patient recovers with a fibroid lung. In either case the possibility of the implantation of tubercle bacilli is not likely to be forgotten.

In the Obstetrical Section of the Royal Society of Medicine Dr. Turner of Ryde detailed a case of hysterectomy sixty-three hours after labor for a necrosed suppurating subperitoneal fibroid in a primipara, aged 32, who had been married thirteen months. The fibroid was diagnosed when she was pregnant about two months, was attached to the uterus by a very broad base, and could not be removed without terminating the pregnancy, so it was decided to let it go until term and operate later. Post-partum hemorrhage had necessitated stripping off the membranes and then a small intramural fibroid was felt. On the third day temperature and pulse rose and with other symptoms progressing sloughing of the tumor was diagnosed and hysterectomy performed. Examination of the tumor indicated that necrotic change must have begun long before labor. Some remarks were made by several members as to the best course in such cases, but all seemed to agree that Dr. Turner had followed the right course.

Dr. Lewers then read an account of a case of tumor of the right broad ligament, springing from the uterus and probably developed from Gärtner's duct, in a primipara of 47, who had noticed a swelling, interference with micturition, etc., for about a month. On opening the abdomen the cyst covered by the ligament was seen and punctured, two pints of thick, dark fluid being removed. Enucleation was easy up to the right side of the uterus at the level of the os. Here it was attached by a pedicle an inch in diameter. This was divided with scissors and the left appendages showing signs of disease were removed. The uterus was retroverted, otherwise normal. Uninterrupted recovery followed. The microscopic examination supported the conclusion that the tumor arose from the intrauterine portion of Gärtner's duct.

This view was confirmed by Dr. Maxwell, who said at first sight it looked like an intraligamentous fibroid which was undergoing cystic degeneration, but the microscopic sections warranted the view that it was developmental and arose in the duct.

The Hon. Arthur Hill Trevor de Montmorency, M.D., T.C.D., died on New Year's day. He was the youngest son of Viscount Mountmorres, born in 1846, educated at Trinity College, and graduated, both in arts and medicine, B.A. 1868, M.B. 1873, and M.D. two years later. He was also L.R.C.S.L. 1873.

The death is announced of Dr. John Holmes Joy, J.P., aged 68, coroner for East Staffordshire. He took M.A., M.D., and T.C.D. in 1865. He was district surgeon to the N. W. Railway and formerly president of the Midland Medical Society. He was also magistrate for the counties of Warwick and Staffordshire. He wrote some papers on hernia and on prolapse of the bowel.

OUR LETTER FROM THE PHILIPPINES.

(From Our Regular Correspondent.)

SUPPRESSING AN OUTBREAK OF CHOLERA—INTESTINAL PARASITES—MEETING OF THE PHILIPPINE MEDICAL SOCIETY—RAISING OF THE QUARANTINE AGAINST AMOY.

MANILA, P. I., November 26, 1909.

DURING the past week an explosive outbreak of cholera occurred in Cebu, which for a time threatened to assume pandemic proportions, and even at this writing this danger is not altogether past. For the ten days immediately preceding November 12 Cebu was believed to be entirely free from cholera. On this latter date

ten cases suddenly occurred, the next day the number rose to 43, the day following to 44, and on the 15th the number of cases reached 73. On investigation it was soon found that the cases were mostly confined to one section of the city. This pointed to a local water infection. Samples taken from several wells showed vibrios to be present. Energetic measures were at once taken to combat the outbreak. A 3 per cent. carbolic acid solution was made of the water in all the wells in the infected district, and this was then pumped out, and by the means of hose as large an area as possible of the ground surface near the wells was flooded with this carbolic solution. This no doubt did much to eliminate any ground pollution that may have existed. The wells were then closed. Distilled water was distributed. Hospitals were established and the sick isolated therein. Public closets were hastily built and these, as well as all private closets in use, were disinfected at frequent intervals. A burial corps was organized. A house-to-house inspection was made at least once daily; all infected houses were promptly disinfected. All of these measures were fairly under way on the 14th, and on the 16th the daily number of cases dropped to 42, on the 17th to 36, on the 18th there were 18, and on the 19th the number was reduced to 5.

The success which attended this campaign again shows in a most forcible manner what can be accomplished by modern prophylactic medicine when its principles are intelligently applied. The island of Cebu, with its population of over 800,000, is one of the most densely populated sections in the Philippines, and unless this outbreak had been most promptly controlled the ravages which cholera would have caused among a people the great majority of whom eat with their fingers and drink unsterilized surface water can well be imagined. In this instance it was impossible to quarantine the contacts and many of them are known to have proceeded to the nearby towns. Two towns have already been reported as being infected, but owing to the timely advance warning which was sent out the first cases were promptly found and isolated and no great spread is anticipated.

The complete figures of the commission which the Bureau of Health put into the field in June at Las Piñas, Rizal Province, for the purpose of ascertaining the percentage of intestinal parasite infections, particularly the hookworm, terminated its labors September 30, and the complete figures are now available. The commission was headed by Medical Inspector Rissler of the Bureau of Health. Six thousand and eighteen persons were examined. Of these 31.30 per cent. were adult males, 42.22 adult females, and the balance, or 26.48 per cent., were children. The total number of positives for some form of parasite was 89.84 per cent. The infections in their order of frequency were as follows: Ascaris, 77.22 per cent.; trichuris, 53.42 per cent.; hookworm, 11.15 per cent.; oxyuris vermicularis, 4.95 per cent.; monads, 3.85 per cent.; strongyloides, 2.24 per cent.; ameba, .4 per cent.,; balantidium coli, .15 per cent., and taenia, .066 per cent. Of the total number 394 males, 241 females, and 42 children had hookworm infections. From the foregoing it is apparent that the percentage of infections is almost twice as great among males as among females. Probably the most striking thing in connection with these figures is the fact of the total number of over six thousand persons examined only 10.16 per cent. were free from parasites and that over half of the people harbored two or more different parasites. Another factor of interest is that the total number of hookworm infections is about the same as that found by the Tay Tay Commission, of which mention has several times been made in these columns. This in spite of the fact that the Tay Tay residents live upon clay soil and the Las Piñas residents upon sandy soil.

The regular monthly meeting of the Manila Medical Society was held at the Philippine Medical School at 8:30 on the evening of November 1. The following papers were read: "An Improved Operation for Hallux Valgus, with Exhibition of Cases," by Captain Keller, U. S. A.; "Remarks on the Surgery of Cerebral Birth Hemorrhage," by Dr. Gilman; "Importance of Early Diagnosis of Carcinoma and Exhibition of Specimens of Carcinoma of Cervix Uteri," by Dr. Guazon; "Remarks on Compound Fracture," by Dr. Schiffbauer; "Successful Surgical Treatment of Acute Free and General Peritonitis," by Dr. McDill.

On account of the fact that both plague and cholera have disappeared, according to the report made by Passed Assistant Surgeon Foster of the Public Health Marine Service, who is stationed at Amoy, the special quarantine restrictions which have heretofore been imposed upon vessels coming from Amoy to the Philippines have been removed.

Progress of Medical Science.

Boston Medical and Surgical Journal, January 13, 1910.

Antityphoid Inoculations Conducted at the Massachusetts General Hospital.—L. H. Spooner details his experiments at this institution for the past few years. One hundred and three people have been inoculated; 74 were hospital nurses, 9 house officers, and 6 ward tenders; 14 were inoculated at the naval hospital. Of the entire number, 6 reacted in solutions of 1 to 10; 14 in 1 to 25; 56 in 1 to 50; 26 in 1 to 100, and 1 in 1 to 500. Since inoculations have been started no cases of fever have been contracted among the hospital officers, nurses, or ward tenders, or in those inoculated at the naval hospital. It is impossible to say how strong an immunity is acquired through the inoculations or how long it will last. About 4 per cent. of all typhoid patients become chronic carriers of the disease. No matter, therefore, how careful we may be as to our supervision of water and milk supplies, there will always be danger of the disease arising through these media. Those like hospital residents who are brought into close and prolonged contact with the malady should submit to inoculation, as should also those who plan a journey into regions known to be infected. Finally, inoculation is likely to become advisable and more or less general in districts where the disease is epidemic. It would seem to be appropriate for other members of a family in which the disease is already present. It is possible that carriers may be eliminated by some method yet to be discovered, but this is at present a matter with rather a hopeless outlook.

Opsonic Therapy in Pyorrhea Alveolaris.—L. S. Medalia has carried out this plan of therapy at the Tufts Medical School for the past three years. His general conclusions are as follows: (1) The opsonic index as a means of diagnosis, although not absolutely mathematically correct, gives us a clue as to the probable bacterial infecting agent in obscure cases. (2) Where it is possible to obtain cultures, the bacteriological findings establish the diagnosis without having to resort to the index. (3) In certain simple infections where the probable infecting agent is known the treatment may be begun immediately with stock vaccine without waiting for cultural or opsonic findings. (4) In a large majority of cases the stock vaccines will give good results excepting in cases of colon or streptococcus infections, where autogenous vaccine is necessary. (5) The use of the opsonic index in treatment is not absolutely necessary, but is to be recommended to determine from time to time the state of progress of the patient under treatment. (6) Vaccine therapy is very satisfactory in cases of staphylococcic and pneumococcic infections, especially the former, is successful in the majority of cases of colon and streptococcus infections, is of value in tuberculosis of the lungs where the secondary infection could be determined and treated with its specific vaccine, has been found to be of great value in gonorrheal arthritis and of some value in acute urethritis and other localized infections due to the gonococcus. (7) The proper application of the opsonic method of treatment in Riggs' disease has yielded most satisfactory results, and a great deal is hoped from its application in the future.

Reproduction of Pain as a Means of Making Differential Diagnosis.—H. T. Hutchins says that one must know normal sensibilities before pathological ones can be appreciated, and all examinations made with the definite purpose of acquiring this essential knowledge will in time prove of the greatest value. Thus, pain in the vermiform appendix is reproduced by making pressure along the descending colon in the direction of reverse peristalsis, thus forcing the gas back toward the cecum and appendix, distending these organs; confining the gas by pressure of the left hand, a sharp tap with the right hand over the distended colon will reproduce the patient's pain on the cecum and appendix in cases of acute and chronic appendicitis. This method has differentiated between an appendix abscess and a retroperitoneal perinephritic abscess. A device has been perfected for inflating the stomach and duodenum in an attempt to reproduce pain in ulcer conditions. The abdomen is opened under gas or local anesthesia; a small opening is made into the stomach, the device (gastroscope) introduced, and the organ distended with

air through the instrument; a gaseous distension of the organs is brought about, and the conscious patient is able to identify any reproduction of pain which may occur. The trouble is thus located, a general anesthetic given, and the necessary operation performed. The renal pelvis may be artificially dilated with bland fluid for the sake of differentiating pain, and for a similar purpose different portions of the urethra may be distended. The same principle may be applied to locate the lesion in cystitis, etc. Pain in all these conditions is our most common and leading symptom. The reproduction of a pain whose nature and origin we thoroughly understand is a helpful step toward a correct diagnosis. But we must first know the normal sensibilities of the various organs. Gentle manipulations of the various pelvic organs give us familiarity with them, along with a knowledge of their shape, size, position, and consistency. When we chance to cause pain we should note its exact nature and location and inquire whether the patient has ever experienced that particular pain before. In a differential diagnosis between pain in the ovaries, appendix, bladder, or ureter such knowledge is of the utmost importance, and the more we learn the more readily will we be able to differentiate disease arising in each viscus. If we can reproduce the patient's former pain we can judge on what organ it has arisen, and differentiate more accurately diseases with symptoms closely resembling one another.

New York Medical Journal, January 15, 1910.

On the Presence of Acid-Fast Bacilli in Distilled Water.—R. C. Rosenberger replies to his critics who asserted that his alleged discovery of tubercle bacilli in the blood was merely the discovery of acid-fast bacilli in the distilled water used in laboratories. He has examined sixteen specimens of such water taken from various Philadelphia laboratories. In none of them were acid-fast bacilli discovered, nor bacteria of any other kind. Similar results followed examination of various waters in the tuberculosis department of one of the Philadelphia hospitals. Nor was it possible to find any traces of the so-called citrate bacillus. In fact, his rejoinder is a complete denial of the justness of the statements of his critics. He refers to his former studies, claiming them to be accurate. He has also found tubercle bacilli in the blood of apparently healthy persons, and confirmed the discovery in at least one case, the truth of the statement being borne out by the subsequent course of the case. He is still of the opinion that tubercle bacilli are present in the blood of every case of tuberculous disease of the lungs or other viscera. Many other observers have, he claims, confirmed his findings of bacilli in the blood, but have hesitated to publish their findings on account of the great hue and cry raised by certain of his critics. If bacilli were not in the blood, he says, how would they appear in the urine and feces without demonstrable lesions of the kidney or intestine? Examination of the blood for bacilli requires laboratory skill and experience. He makes a protest against the loss of confidence in distilled water. If prepared in the way directed and supposed to be sterile and subjected to the usual tests, it is not pure, pray, what is pure? Where the water is freshly distilled and placed in sterile and clean receptacles there need be no fear of any contamination whatever, and especially from an acid-fast organism. When the distilled water is mixed with sodium citrate, sterilized in the autoclave, and blood taken in an aseptic manner is introduced into this sterile solution, as no one at the present time believes in spontaneous generation, there is no other deduction to make than that the organism is in the blood. It has been claimed that acid-fast bacilli are often present on the hands of the investigator, but this can readily be explained if contamination occurred with some tuberculous material, or if a person suffering with tuberculosis were carelessly to wipe the mouth with the hand and thus infect that member. Slides are often examined carelessly, but minute attention to all details is called for in such work, as the author has in mind. He refers to the literature which has been written in criticism of his position.

Inoculations of Bacterial Vaccines for Acute Rheumatism.—G. A. Persson has employed this form of therapy in 68 cases. Of the *Streptococcus rheumaticus* cases, 32 were cured, 8 improved, and 7 unimproved; of *Staphylococcus pyogenes aureus* cases, 7 were improved and 4 unimproved; of colon bacillus cases, 1 was improved and 3 were unimproved. The bacterial vaccine which was used in all these cases was prepared in the following manner: A desired microorganism was grown in a media consisting of eighty parts of sea water with a specific gravity of 10.15 which had been sterilized by filtration, and twenty parts of a five per cent. solution of nucleanic acid, allowed to develop in the incubator for forty-eight hours, when proper dilution with the sterilized sea water was made to form a suspension of 20,000,000 germs to the cubic centimeter. It was then exposed to thermal death point for thirty minutes. Each patient received a daily inoculation of 1 c.c. or 20,000,000 germs. The author discusses the various theories of rheumatism. He believes that it is an infection, but adds that there is at present no general agreement as to the exact nature of the infection. Current theories include the specific bacillus theory, not yet absolutely confirmed, the septicemic theory, the disease being due to some staphylococcus or streptococcus, the diplococcus theory, and lastly, that the disease is due to some unknown cause. The main arguments for and against each of these theories are summarized. The author does not stand committed to any one of these views. He says that a point well worthy of emphasis is the fact that immunity is to-day but an accidental condition produced by an unknown force at work in strange environments. When this force is harnessed by man's ingenuity and with scientific guidance can be directed into the avenues of pathological changes in the human body, this condition will no longer be accidental, but will come within the power of the physician to wrap nature's cloak of protection in gentle folds about the susceptible individual and place his suffering patient upon that high level of physiological perfection which we to-day call immunity.

Journal of the American Medical Association, January 15, 1910.

Radical Treatment of Epithelioma of the Lip.—J. C. Stewart discusses the radical treatment of lip cancer. He states that local removal of lip cancer should never be done, because it is impossible to exclude lymphatic involvement in any case. Radical operation embodying the principles laid down is the only sure way to obtain the best results for our patients, our own reputations, and the credit of the surgical treatment of cancer. Even in recurrent cases much can be done, and these patients should, when the extensive involvement of irremovable soft parts does not preclude, be given the benefit of a carefully executed operation on the same lines. The article is illustrated.

Palatopharyngeal Adhesions.—A full discussion of this very troublesome complication is given by J. O. Roe. These palatopharyngeal adhesions may be, he says, (1) congenital; (2) simple inflammatory—catarrhal; (3) due to excoriation of the mucous membrane by acrid discharges; (4) local manifestations of the exanthemata; (5) local manifestations of constitutional diseases, syphilis, tuberculosis, and so-called scrofula; (6) due to traumatism. The largest number are due to syphilis, and a distinctive difference between adhesions due to this cause and the others mentioned is that the former is usually characterized by marked cicatricial contraction from extensive destruction of tissue, while the others are simple adhesions without marked distortion. These adhesions would be much more frequent, doubtless, were it not for the constant movement of the muscles of the parts in breathing, swallowing, and speaking and other actions of the body, and also the separation of the parts by mucus discharging from the posterior nares. The rapidity with which adhesions form when the ulceration is healing is remarkable. Complete union of the pharynx with the palate is exceptional; there is almost invariably a small opening. The degree to which the ears and hearing become affected varies according to the amount of involvement of the Eustachian tube, and the voice sometimes may be comparatively unaffected. The characteristics of the adhesions differ according to the various causes, those from syphilis being dense and fibrous, while those from purely inflammatory conditions usually contain little fibrous tissue and are mainly muscular, and sometimes there is simply an adhesion of the mucous surfaces. In case of destructive ulceration the muscular structures may be extensively altered and replaced by connective tissue in parts. In the treatment of these conditions it is important to delay any operative procedures until all ulceration or inflammation has subsided. Early recognition of the constitutional conditions causing adhesions is important, but after ulceration has occurred, as in syphilis, it can only be arrested in spite of constitutional treatment. Since the laryngoscope and rhinoscope have come into use the etiology and characteristic conditions have been generally well known. The chief difficulty, however, does not exist in the operation of freeing the adhesions, but in keeping them free. The usual method of operating is with the knife, but the readiness with which cicatricial tissue reunites has led some operators to perform dissection of this cicatrix, some-

times with success. The galvanic cautery has not given good results, and in 1883 Smith and Delavan proposed the use of monochloracetic acid, which heals up under the scab after its use for cauterization. The immediate result is good, but contraction may occur later. Other methods, such as drawing the palate away and fastening it to prevent contact, the use of permanent obturators worn for considerable periods, etc., have been employed. The most decided step in advance, Roe says, was made by Nichols in 1890, when he proposed the plan of introducing silk sutures at the side of the palate and allowing the sutures to remain *in situ* until a healed channel had formed around them; the palate is then liberated between these two channels, great care being taken not to wound the outer wall of the channel. Roe has employed this method in three cases with gratifying results, modifying it only by the use of a silver wire instead of the silk. In a fourth case it failed, and he devised a plan of covering the raw surfaces at the outer angles with flaps of mucous membrane taken from the neighboring parts at the sides. These flaps were made of sufficient length to cover the entire extent, vertically, of the liberated surfaces and were stitched in place by sutures passed directly through the palate.

Renal Activity and Its Tests.—S. W. Schapira criticises the older and still ordinarily used tests for impairment of kidney function—the search for albumin and casts, the determination of urea, of the amount of chlorids and of uric acid and phosphates—as not giving reliable information. The amount of urine is of some value in determining chronic kidney disease, and cryoscopy, while of some utility, is influenced by the amount of water ingested and is impracticable under too many circumstances for general use. The tests that he here discusses and has experimented with himself for a number of years are based on the principle of introducing foreign substances into the human body and noting the time of their elimination by the kidneys. The results of his studies lead him to the following conclusions: "1. They confirm the views of those who believe that little value can be placed in the presence of casts and albumin alone, as evidence of kidney disease, for my statistics show that one in every fifteen persons walking the streets has albumin or albumin and casts in the urine. 2. The most accurate test for permeability of the kidneys is phloridzin in connection with ureter catheterization, although it is sometimes a very tedious process. Next of importance is the indigo carmin, which is a very quick test, and last, methylene blue. 3. The relationship of transient glycosuria to impaired kidney function when found in one kidney is deserving of study and investigation. 4. My investigations tend to show that the diagnosis of kidney disease by clinical tests and clinical symptoms in most instances is not borne out by the examination with phloridzin, methylene blue, and indigo carmin."

Acquired Intestinal Diverticula.—The theories of the formation of acquired intestinal diverticula are discussed by Guthrie McConnell, who says that the importance of these dilatations of the intestinal wall has been only recently fully appreciated. A number of instances have been reported in which they have produced serious symptoms. From the study of a case in which multiple diverticula were found in the intestine at autopsy, and from the review of the literature of the subject, he concludes that they are formed late in life as a result of localized weakened areas in the muscular tissue of the gut. There does not appear to be sufficient evidence that they are due to any congenital abnormalities of the muscularis, and they have never been reported as found in children. The theory that they are the result of a relaxation of the intestinal wall at the point where the blood vessels enter also seems unproved, particularly as they have been found on the convex surface of the wall, and they also contain muscular tissue which would not be present if the diverticula were simply hernial protrusions of the mucosa and submucosa. The theory, therefore, of Beer and Telling seems most reasonable.

Urine Examination.—J. E. Dale has used the following routine in urinary examinations for the past six years and recommends it as useful as a systematic method for detecting the rarer urinary proteins. He claims no originality in any single step of the method, but only that it is a convenient grouping of well-known reactions. Any examination for these bodies presumes a chemically pure acetic acid and clear urine. If the urine is turbid it will be well to add a little magnesium carbonate in fine powder, allow it to stand a few minutes and filter. "1. A portion of the clear urine in a test-tube is acidified with acetic acid; a clouding indicates nucleoalbumin. If a precipitate forms, it should be filtered. 2. (A) A portion of the filtrate of No. 1 (or if No. 1 be negative, the clear acidified urine) is added slowly to a portion of a solution of common salt, a precipitate may be any of the following—any albumose (except deuteroalbumose), histon, or globin. (B) If a precipitate is not formed, the addition of urine is continued until it is in excess of the salt solution; the upper third is shaken and boiled; a clouding indicates serum albumin. (C) If a precipitate is formed, it should be filtered, care being taken that the urine has not been added beyond the point at which it is saturated by the salt solution. The filtrate should be boiled. A clouding indicates serum albumin. (D) If a positive reaction is had in A, it is my practice first to saturate a portion of the original urine with saturated salt solution without adding acetic acid to determine whether a precipitate is formed in neutral solution, and, second, to determine whether the body present is one of which loosely combined sulphur is a characteristic, using Boston's method (equal parts of urine and saturated solution of salt, rendered strongly alkaline with potassium hydrate, are boiled in the upper third, and 10 per cent. lead acetate added, drop by drop, while boiling continues, a heavy black precipitate showing loosely combined sulphur). No. 3. A few drops of the original urine are added, a drop at a time, to a considerable quantity of clear water. Milky streaks in the track of the drops indicate globulin (Robert's method). No. 4. (A) A portion of the original urine is acidified with acetic acid and filtered; the filtrate is then rendered faintly alkaline with ammonium hydrate and boiled for a few minutes, then filtered. The filtrate may contain peptone or deuteroalbumose. (B) The second filtrate from A is saturated with ammonium sulphate and boiled. A white precipitate indicates deuteroalbumose (yellow or brownish ammonium urate). (C) B is filtered and filtrate examined for peptone; if deuteroalbumose has been found, the saturation with ammonium sulphate must be complete and the boiling decided to assure its separation." He gives the reasons for the steps outlined above and says that, while the description may seem complicated, it is really simple, and in the vast majority of cases nothing, unless it be serum albumin, is likely to be found. The presence of the rarer albuminoids is indicated, but the details of their identification, especially of the albumoses, are not given, as being beyond the scope of the paper.

Trichiniasis.—J. L. Hirsch reports a house epidemic of trichiniasis caused by eating raw ham and involving five adult members of a family of eight, the other three not having partaken of the ham. The first symptoms showed themselves about the sixth or eighth day after the injection, probably at the time when the larvæ had fully developed. Edema of the eyelids was observed in all, and in three it was the first symptom. All had abdominal cramps, very severe in two. Nausea and vomiting was observed in two cases. Troublesome constipation was the rule; there was no diarrhea. Muscle pains were a prominent symptom. In two cases the temperature was constantly high. In the others there were intermissions. None of the patients had chills. Pulse and respiration followed the same course as the temperature. The urine was negative, and no parasites were found in the stools. Urticaria was present in one case in an aggravated form which lasted three days. In only two cases was there a leucocytosis, and that in moderate degree. There was, however, in all an eosinophilia, varying from 18 to 45 per cent., but not in relation to the severity of the infection. As regards treatment, the author thinks that free purgation, if sufficiently early, may do some good, but very little after the worm has penetrated the mucosa. Relief of the muscle and abdominal pains with opiates and hypnotics to secure sleep is about all that can be done until Nature takes care of the parasite. All the patients recovered, the duration of the attack varying from two to six weeks.

The Lancet, January 8, 1910.

Some Cases of Congenital Intestinal Obstruction.—In the experience of N. I. Spriggs, he has come across the following cases: Septum in ileum, atresia of ileum, 2 cases, atresia of ileum with loss of continuity of bowel, multiple atresia of the jejunoileum, atresia of the duodenum, and obstruction due to abnormal arrangement of the mesentery. He says that congenital intestinal obstruction is most often complete, as happened in all his cases except the last, and that it is also generally single. The position of the break is most often in the ileum, especially in its lower portion. The obstruction is most often in the shape of a septum, often obliquely placed, while more rarely there is a longer or shorter fibrous band connecting the ends of the bowel at the site of obstruction. Below the obstruction the bowel is in a very contracted condition; above the obstruction the bowel is naturally very much

dilated. The content of the contracted bowel is a very little, thick, and tenacious mucus. As to etiology, there are two main views, the developmental and the inflammatory. Other views assume the presence of a fetal volvulus, while still other supposed causes of the condition are intussusception, contraction from ulceration, embolism, or thrombosis of the mesenteric vessels and enlarged valvulæ conniventes. No one theory can cover all cases. In most instances the obstruction has not been diagnosed. Vomiting is usually the most marked feature and is present from birth. Constipation is generally absolute, while abdominal distention develops in the course of a day or two. Intussusception, volvulus, internal hernia, etc., may occur within a day or two of birth. The prognosis is absolutely bad. Enteroanastomosis has been done six times. No case of recovery has been recorded. It is doubtful whether operative intervention should be attempted. Two lines of treatment are open if it is decided to operate. First, to perform enterostomy above the obstruction and so drain the bowel, and, second, to do some kind of enteroanastomosis, thus connecting up the bowel above with that below the obstruction. The latter is the operation of choice if when the infant is seen it is in good condition. If the child is very feeble, simple drainage of the distended bowel should be undertaken as early as possible with only local anesthesia. If the obstruction is not too high up in the small intestine, so that there is a considerable absorbing surface left functionating, the infant may recover somewhat in the course of a few days, and then enteroanastomosis may be undertaken with a better chance of success. In the case of duodenal obstruction, simple drainage cannot be performed, and gastroenterostomy is the only line of treatment. The author gives the details of the cases which have come under his own observation and the autopsy findings (illustrated) in each case.

The Nature and Treatment of Angina Pectoris.—Ten cases are reported by A. Morrison. He says that we have not as yet a complete knowledge of the anatomy of this condition. Endocarditic cases may be found in the young, while degenerative cases generally affect later life. Thrombosis of a coronary artery may be associated with a persistent and severe cardiac colic. The condition may arise from a partial cramp of the cardiac musculature. It may be a general psychical disorder supervening on local anginous symptoms. Hence the character and situation of the conditions which originate angina vary, and if like other viscera the heart is endowed with low sensibility to handling and other modes of external irritation, it may in the presence of a lesion of its internal surfaces or severe stimulation of its nervous endowment, by compression or otherwise, reveal evidences of sensibility as well marked as do other viscera in their interior and under circumstances which may be regarded as analagous. The author believes that in all marked cases of angina pectoris the site of referred pain is one or other portions of the heart itself. Peripheral vascular spasm as a preliminary event is rare. It may occur as a secondary and aggravating event, as also may a condition of vascular laxity due to inhibited ventricular systole, the consequence, he believes, of pneumogastric shock. The attack of angina in valvular disease is frequently relieved by the nitrites. In non-valvular angina we need morphine and atropine, or even a general anesthetic. All forms of over-exertion must be avoided. Good results sometimes follow the iodides and mercurials. The attacks with valvular disease frequently occur during period of defective compensation when we are not dealing with a hypermyotic heart. In this series the blood content of the heart plays a part. The treatment, therefore, of this condition of comparative cardiac failure on recognized lines is that indicated during periods of greater anginous distress. In the case of the hypermyotic heart when anginous symptoms supervene, tend to increase, and become persistent, further measures may become necessary. The cause of death in angina pectoris is, according to the author, the inhibition of cardiac action by the shock of pain. The heart may rapidly cease to beat and die in diastole, or death may be postponed somewhat longer, the organ passing into a feeble tachycardia very suggestive of the fibrillary tremor in the cardiac action of animals killed experimentally by intensive or repeated electrical shocks.

Recent Researches on the Anatomy of the Heart.—A. Keith and I. Mackenzie refer to a paper of the former, in which a little peculiar mass of muscle and nerve scarcely bigger than a grain of wheat was described as constantly found at the termination of the superior vena cava in the right auricle and to which he gave the name of the sino-auricular node. He supposed this mass to be the starting point of the heart's contraction. Recent experiments on various of the lower animals tend to show that these masses are really neuromuscular contacts. As one ascends the scale of animals this concentration of tissue becomes more marked. In the mammalian heart the sinoauricular nodal tissue is concentrated on the right auricle chiefly along the sinonodal junction and in front and on each side of the superior vena cava. The node is situated in the septal wall of the right auricle. The single strand of muscular communication now known as the auriculoventricular bundle is peculiar to the mammalian heart. One of the chief results of the author's investigations has been to impress on them the necessity of studying the special musculature of the heart in relation to the abundant nerve supply of that organ. The excitable regions of the heart are those where the nerves come into a specially direct connection with the specialized tissue they have called nodal. The nerve plexuses at these sites are so zigzag that they could not possibly sever all nerve connections between the auricle and ventricle. They believe that an entirely new description of the cardiac nerves is necessary and that there must be a fundamental differentiation into those nerves which supply the venous base or commencement of the heart supplied from the lower cervical sympathetics and those which end in the terminal end or arterial base of the heart.

British Medical Journal, January 8, 1910.

Lime Water in the Treatment of Verruca Plana.—D. Kennard reports the case of a young woman who had at least from 300 to 400 warts on the back of each hand, but none on the face or other part of the body. The various calcium and arsenical preparations were given without effect. Cauterants also failed. She was sent to an eminent skin specialist, whose various remedies were also useless. Finally he tried scraping each wart and applying pure carbolic acid. This had the desired effect on each wart treated, but in the meantime fresh warts appeared, and the patient returned to the author quite discouraged. Local treatment appeared useless, as fresh crops kept coming out. Finally he fell back on an old remedy which has fallen into disuse. He ordered the patient to take half a pint of lime water daily for a week. In the course of four days each wart disappeared, and for the last two months since this treatment was tried, no fresh outbreak has occurred.

Excessive Liability of European Women in Africa to Trypanosomiasis; Its Cause and Prevention.—Sir Patrick Manson calls attention to the small number of European women in Africa, but also to their excessive liability to trypanosomiasis. He attributes this to their continuance of wearing the same kind of clothes as at home. Of five cases of the disease, three gave a history of being first bitten on the leg. Immediately on being bitten the part attacked became swollen and painful, and within a few days the usual constitutional symptoms of fever and eruption appeared. In one case the infecting bite was on the finger. These facts indicate that the petticoat and skirt should be discarded for some other type of garment and one more resembling the male trousers. Skirts and petticoats should be discarded in Africa, and a bloomer costume or loose trousers of some sort should be worn, the tops being securely tied around the boots, as well as loose sleeves securely fastened around the wrists. Men, too, should have their jacket sleeves thus fastened. Thus, in the author's opinion, the great risk to which a European woman is exposed in her usual attire in Africa may be avoided.

The Frequency of Adenocarcinoma of the Body in Fibroid Tumors of the Uterus.—The experience of J. M. Munro Kerr is based on the results found in 200 abdominal hysterectomies. In this series he has found malignant disease on nine occasions, sarcoma two, adenocarcinoma of the uterine body six, and carcinoma of the cervix one. Regarding the six cases of adenocarcinoma, in four the fibroid tumors were of large dimensions, and in two small and multiple. On consulting the writings of other operators he finds records of very similar experiences. An interesting fact in connection with these cases of malignant degeneration is the relative frequency of the occurrence in the late decades of life. As a rule it is the fiftieth year before the malignancy is reached. The question of temporizing in these growths suggests itself. In case of adenocarcinoma curettage of the uterus and examination of the scrapings will give us definite information. But sometimes the uterine cavity is difficult to explore by reason of its distortion by the tumors and in sarcoma curettage is valueless as the malignant degeneration rarely

commences in the endometrium. Pain is always suspicious and in the author's experience it is especially common in adenocarcinoma which has invaded fibroids as compared with cases in which the lesion attacks an otherwise normal uterus. An increase of bleeding is also very common and often there is a distinct increase in the swelling. Lastly there is the important fact that in a large proportion of cases malignancy does not occur till the fortieth year, when the uterus is of little physiological value and when one has naturally very little compunction in removing it. By the history, age of the patient, and curettage, we were able generally to recognize malignancy and can therefore allow a certain number of fibromyomata to remain unoperated upon. Hemorrhage and pressure signs indicate immediate intervention, but what we wish to arrive at is an opinion on the fact that intervention is necessary even if these ordinarily recognized signs are not present. We wish to try to recognize the cases in which malignant degeneration or invasion has already begun.

Berliner klinische Wochenschrift, December 19, 1909.

The Medical Treatment of Gastric Ulcer.—Weïntraud says that one may expect good results from the surgical treatment of gastric ulcer in cases with chronic recurrent hemorrhages by interval operation; in cases of gastric motor insufficiency from pyloric ulcer or scar, in pyloric stenoses and hour-glass stomach, and in cases with subphrenic abscesses. That the usual simple cases, *i.e.* cases without peritoneal involvement, usually recover well, is shown by the author's series of 134 cases. Although two-thirds had definite bleeding and a smaller number had hematemesis sufficiently severe to make it appear that the patient was in a critical condition, not a single case died of the hemorrhages. Regardless of appearances, the author gave a good prognosis, and allowed an operation to be performed only when there was some direct indication for it.

Deutsche medizinische Wochenschrift, December 23 and 30, 1909.

Experimental Sleeping Sickness.—Spielmeyer has made careful examinations of the central nervous system of two dogs which were inoculated with the *Trypanosoma gambiensis,* from which he concludes that the brain of such animals show exactly the same lesions as are found in sleeping sickness in man, and are considered characteristic for the latter disease. In one case the author was dealing with an early case; in the other with one in the very advanced stages of the central nervous system process. The anatomical picture, especially in the early case, reminds one very much of the findings in progressive paralysis of the insane. In the second case, in which death occurred a year and a half after the original inoculation, the trypanosoma seemed to disappear from the blood several weeks before the onset of the symptoms referable to the central nervous system.

Review of 2,000 Operations for Appendicitis.—Schnitzler discusses his studies of 2,000 operations which he has performed for appendicitis. He concludes with the following summary. Appendicitis, which is not increasing in frequency, is, as a rule, of enterogenous origin. The hematogenous occurrence of the disease is a rare exception. Even the cases secondary to tonsillitis are usually not of hematogenous origin. Fecal stones are of very great influence, not only in the course of the attack, but also as a cause of the disease. The diagnosis of chronic appendicitis without acute attacks is very uncertain. Among the most common causes of error in diagnosis, to which especial attention must be paid, is the fact that latent tuberculosis, especially of the lungs, not infrequently causes pain and tenderness in the iliocecal region. Operation within forty-eight hours is to be recommended in every case which shows any single severe symptom. Cases seen in the later course of the disease must be considered on their merits. Large abscesses must be incised through the shortest channel; those in Douglas' cul-de-sac should be opened through the rectum. The interval operation is to be advised if a single definite attack has been experienced. It is also recommended after the most severe attacks, for the idea that in serious attacks the appendix is destroyed is false.

Functional Diagnosis of the Intestines.—Brugsch says that the functional diagnosis of the intestines includes the activity of the bile, pancreatic secretions, and the secretions of the intestinal wall itself, besides the motility of the bowels. In intestinal diagnosis we are able to employ the end products only, as found in the stools, the portions of the food which have not been absorbed. The purpose of functional diagnosis is not only to find what part of the food has failed in digestion and absorption, but what particular portion of the intestines or its contributing organs is responsible for the failure. The first point is to estimate what proportion of the ingested food has been utilized. This is done by giving a simple nitrogenous, fat, and carbohydrate diet of definite quantities preceded and followed by 0.3 gm. of carmine. The diet used consists of two liters of milk, fifty grams of butter, and 100-200 grams of white bread. This is easily analyzed and the various constituents may be increased at will. A normal man on this diet wastes not over 5-6 per cent. of nitrogen, 10 per cent. of fat, and no carbohydrate. If the fat is increased or large amounts of meat added this percentage increases somewhat, but not in proportion to the amount taken. In practice this analysis of the chemical constituents of the stools is difficult and tedious, and is used only when the microscopic examination shows increased fat, or fatty acids, meat remains, or undigested starch. As to the diagnostic value of such an examination, animal experiments and clinical observations have shown that in obstruction of the bile duct, 40 per cent. of the fat is lost, but not over 11 per cent. of the nitrogen. If the pancreas is removed, no fat is utilized and only 44 per cent. of the nitrogen. In a dog ligating the pancreatic duct causes no injury to the absorption power, until the pancreas has atrophied. The same has been shown clinically that benign obstruction of the pancreatic duct does not reduce the absorption ratio of the food, fat stools appearing only with atrophy, abscess, or cancer. In these conditions fat waste usually reaches 60 per cent. and nitrogen waste 20 per cent. Over 50 per cent. of waste of fat in the absence of jaundice suggests pancreatic diseases, if amyloid disease and tuberculosis of the gut can be ruled out. Small fat and nitrogen waste in the presence of icterus does not rule out a benign obstruction of the pancreatic duct. Very marked fat waste speaks for pancreatic disease. The demonstration of the ferments, trypsin, erepsin, nuclease, and invertase in the stools are also of value. The trypsin is estimated by extracting the stool with a 1:1000 soda solution, and testing by Fuld's method. The nuclease may be tested by putting the patient on a purin-free diet, estimating the uric acid in the urine, and then after feeding a definite amount of nucleic acid estimating the uric acid increase. The author considers the Cammidge test to be too indefinite in the results for clinical value.

Two Cases of Nævus Vasculosus Cured by the X-Ray.—Schmidt, after reporting two cases, concludes that vascular nevi may be cured by the *x*-ray. There is no fundamental difference between the action of the *x*-rays and radium upon vascular new growths. The *x*-ray has the advantage that a larger area may be treated at one sitting. Among the unpleasant complications of both the *x*-ray and radium treatments should be mentioned the subsequent formation of pigmented patches and telangiectases. This, however, may be absolutely prevented if the erythema forming dose is not surpassed at any one sitting, and if the next treatment is not begun until this has completely healed. Shallow nevi may be cured without scar formation; angioma only with a scar. Electrolysis and the Finsen light are of avail only with very small angiomata and shallow nevi. In all large flat nevi, and especially in tumor forming nevi the *x*-ray is indicated.

Utero-Annexial Sclerosis Outside the Menopause.—Roux de Brignolles describes utero-annexial sclerosis as a disease which occurs in young women during the period of genital activity, occurring even in young girls, as well as during the menopause. Its cause is a repeated congestion of the ovaries at unphysiological intervals. The result is a chronic affection characterized by sclerocystic changes, prolapses and induration of the uterus and ovaries, accompanied by painful phenomena which make the life of the patient so miserable that the only relief consists in removal of the hopelessly diseased organs. Pain is severe both at and between the menstrual periods, accompanied by intercostal and spinal neuralgias, menorrhagias and metrorrhagias, extreme nervousness and irritability, constipation or membranous enteritis, and leucorrhea. Either the patient becomes a nervous invalid, irritable and exacting, or a phlegmatic, characterless individual, refraining from all effort for fear of increasing her sufferings. In either case she is unable to think of anything but herself and her sufferings. The uterus becomes prolapsed and enlarged, and the ovaries prolapsed or adherent. The cause of this condition is not usually infection. It may result from any condition that causes congestion of the genitals, such as constipation, uterine displacements, or tumors. The only permanent relief comes through removal of the diseased organs.—*La Gynecologie.*

Society Reports.

MEDICAL SOCIETY OF THE STATE OF NEW YORK.

104th Annual Meeting, Held at Albany, January 24, 25, and 26, 1910.

THE PRESIDENT, DR. CHARLES G. STOCKTON OF BUFFALO, IN THE CHAIR.

(Special Report to the MEDICAL RECORD).

Monday, January 24—First Day.

Report of the Secretary.—Dr. WISNER R. TOWNSEND of New York reported that the membership, December 31, 1909, was 6,740; 1908, 6,505. There were dropped for non-payment of dues, December 31, 1909, 370; 1908, 374. The membership after removal of delinquents, December 31, 1909, 6,370; 1908, 6,221. The number of deaths in 1908 was 72; in 1909, 98. In 1908 there were 31 resignations; in 1909, 16. The new and reinstated members in 1908 numbered 641; in 1909, 729. The Council at its May meeting passed a resolution permitting members who joined their County Societies after October 1, 1909, to have their State assessments credited to 1910, if they so desired. One hundred and forty-four took advantage of this provision, so that the membership of 6,370 will be increased on January 1 to 6,514, a gain of 348 over the membership on January 1, 1909. The increase in Society membership for the years 1908 and 1909 was encouraging.

Report of the Committee on Publication.—The Directory issued during the month of October contained 266 pages less than the one issued the previous year. This reduction in size was accomplished by the use of a different type and by omitting some of the data of Connecticut and New Jersey. This did not lessen the value of the book to the New York physicians; the New York data were more complete than in former editions.

Report of the Committee on Public Health.—This Committee recommended that the Medical Society of the State of New York declare its opinion that the public health was endangered by the pollution of water courses, and that the legislature should at once so amend the health laws as to make such pollution amenable to the control of the Commissioner of Public Health under proper safeguards. The Committee also recommended that the Society respectfully request the President of the United States and the Secretary of Agriculture to secure an amendment to the National Food and Drug Act by which the use of antiseptic drugs in canned fruits and vegetables and in all preparations from fruits and vegetables designed for human consumption shall be prohibited. Also that the inspection of the commercial food kitchens of the United States by government officers for the purpose of insuring the use of sound materials, cleanliness of methods, and compliance with the law concerning adulterants and the use of preservatives be made obligatory. The Committee also recommended that this Society urge upon Congress and the Senate of the United States the organization under a single bureau, to be known as The Bureau of Public Health, of all the offices and agencies now having duties in any way connected with the preservation of the public health, except only those offices having to do with the protection of the health of the army and navy. With such a bureau established it would be more easily possible to properly correlate the Public Health Departments of the nation, the States and individual communities in the States. Such a correlation was desirable and necessary, for many of the problems confronting many local Boards of Health had a scope which was interstate and national in extent. Without waiting, however, for the consummation of such a plan in its entirety, it seemed desirable to secure in the State of New York a closer relation between the local health authorities and the State Commission of Health.

Report of the Committee on Legislation.—During the year 1909 there were introduced into the Legislature about 225 measures relating to medicine, public health, and sanitation. The Committee on Legislation during the year devoted its energies principally to assisting the Committee on Experimental Medicine in opposing the bills introduced to restrict animal experimentation.

Report of the Counsel.—JAMES TAYLOR LEWIS, ESQ., reported that no year in the history of organized malpractice defense had been so fruitful of results in the stamping out of blackmailing cases as the present one. During no year had the counsel met with such enthusiastic support by the medical fraternity as during the one just ended. Dr. Lewis began the defense of malpractice actions on September 1, 1900. Since that time over 250 cases had come before him, and of that number 138 had been actually tried, none finally lost and one was now on appeal. Not one dollar of damages had ever been paid. This was a result not even hoped for, and the success of organized malpractice defense in the hands of State Societies had been demonstrated. It was interesting to note that during the past year a great majority of the cases begun were by women plaintiffs.

Election of Officers.—*President*, Dr. Charles Jewett of Brooklyn; *First Vice-President*, Dr. Charles Stover of Amsterdam; *Second Vice-President*, Dr. J. W. Grosvenor of Buffalo; *Third Vice-President*, Dr. C. W. Brown of Elmira; *Secretary*, Dr. Wisner R. Townsend of New York; *Treasurer*, Dr. Alexander Lambert of New York.

The next annual meeting will be held at Albany during the third week in April, 1911.

Tuesday, January 25—Second Day.

President's Address.—Dr. CHARLES G. STOCKTON of Buffalo delivered this address. He called attention to the willingness of the people to obey quarantine and other laws, and to follow a certain course of life if the opportunity was given them. There had appeared a greater degree of confidence between the physician and the patient than had ever existed before. It should be remembered that the extent they commanded the public confidence, the greater they assumed the burden of responsibility. The more complete the organization of the profession, the more satisfactory would be the morale of the profession. The decline in sickness had made it difficult for physicians in certain localities to maintain themselves in the social class in which they belonged. This at times offered an excuse for a spirit of commercialism which occasionally showed itself. The patient must trust the physician, and the physician should not allow this confidence to be weakened. The principle of the profession should be: "I will keep faith with my patient." The theory of consultation had suffered from a solution of continuity. Trust should be fostered among the patients, and the best interests of the patient should be kept in sight at all times. A man entered the medical profession to-day not because it was easy, but because it was hard. One had no right to complain of their times or their conditions, but should rejoice that there was an opportunity for battling against obvious evils. There need be no fear that preventive medicine would ever remove the field of labor. It was evident that preventive medicine required the best effort they could put forth, as it at most only meant transferring the activity from one side of the field to the other. The attempt to make medicine luxurious, or to free it from its weight of responsibilities, would defeat its own end.

The Wassermann and Noguchi Complement-Fixation Tests in Leprosy.—Dr. HOWARD FOX of New York reviewed the literature upon the Wassermann reaction in leprosy and then gave the results of his examination in

60 cases, 15 seen in New York and 45 at the Louisiana Leper Home. His conclusions were as follows: (1) A positive Wassermann reaction was frequently obtained in cases of leprosy giving no history or symptoms of syphilis. (2) The reaction was at times very strong, the inhibition of hemolysis being complete. (3) The reaction occurred chiefly in the tubercular and mixed forms of the disease, especially in the advanced and active cases. (4) In cases of maculoanesthetic and purely trophic type, the reaction was generally negative. (5) The value of the test was not affected in the slightest by the results found in leprosy.

Splenomedullary Leukemia: Its Treatment by Roentgen Therapy, with Report of a Case.—Dr. Homer E. Smith of Norwich and Dr. L. A. Van Wagner of Sherburne presented this communication. They reported a case which apparently recovered under the *x*-ray treatment, but which ultimately relapsed. The patient was a woman, fifty-one years old, and she had a leucocytosis of 580,000. She was treated by the Roentgen ray and a solution of the bromide of gold and arsenic. After nine months of treatment the leucocytes numbered 8,030. The question was, would the relapse have occurred if the Roengten ray treatment had been continued. In the use of this treatment they believed that the bulk of their failures was due to the method employed, and not to the agent itself. In the present-day status of Roentgen ray treatment of this disease, it was shown that 25 per cent. of the cases reacted favorably.

Dr. Alexander Lambert of New York said that many of these patients with splenomedullary leukemia who were apparently cured by the employment of the *x*-ray relapsed and speedily died.

Dr. Henry L. Elsner of Syracuse said he was forced to the conclusion that even with *x*-ray therapy they were not going to cure the disease.

Dr. Allen A. Jones of Buffalo said that if these cases were carefully studied, it would be found that there would be a rise and fall in the number of leucocytes while the patient was under no special plan of treatment whatever.

The Diagnostic Value of Eosinophilia.—Dr. Ira S. Wile of New York believed that the differential leucocyte count was the most valuable single hematological procedure. Eosinophilia was a relative leucocytosis wherein the circulating eosinophiles were increased, whether the total number of leucocytes was increased or a leucopenia existed. Eosinophilia was merely a symptom and should be interpreted in the light of full clinical findings at the time the blood smears were secured. From 1 per cent. to 4 per cent. was normal for adults, and from 1 per cent. to 2 per cent, in childhood. Trichiniasis had a high eosinophilia, though it was not pathognomonic, A high count was an early symptom in uncinariasis. If an eosinophilia accompanied an anemia, an examination of the stools for intestinal parasites should be made. Eosinophilia was common in many dermatoses such as pemphigus, leprosy, eczema, etc. The reported eosinophilia seen in pellagra was probably due to intercurrent affections. Any improvement in tuberculosis was accompanied by an eosinophilic increase. Eosinophilia differentiated bronchial asthma from cardiac and renal asthma. Eosinophilia pointed toward malignancy in tumor formations. It might be caused by many drugs, such as camphor, potassium iodide, sodium salicylate, etc. In dementia precox, the administration of thyroidectin seemed to increase the number of eosinophiles. Pus and gangrene might occur despite eosinophilia if the toxic absorption was retarded. The determination of eosinophilia was within the power of every clinician, and Dr. Wile believed it demanded greater attention than was now being given to it.

Some Remarks on Anemias.—Dr. Charles O. Boswell of Rochester read this paper and recited the causes of primary and secondary anemias and gave a brief description of the blood pictures occurring in the various states. Chlorosis was becoming a very rare disease, while there was a gradual increase in the number of cases of pernicious anemia. Cabot believed that chlorosis was gradually dying out. He believed that three years was the extreme life in pernicious anemia.

Dr. Egbert LeFevre of New York called attention to a type of pernicious anemia which went through the stages of a secondary anemia and gradually passed into this pernicious type with an ideal blood picture.

Dr. A. Jacobi of New York said he seldom gave iron or arsenic for a long period of time without the addition of manganese. Chlorosis he did not believe to be as rare as the reader of the paper implied. These cases were not hospital cases and, therefore, ought not to be judged by hospital men.

The United States Pharmacopeia; Its Present Status and Coming Revision.—Dr. Eli H. Long of Buffalo told of the importance of the coming revision of the United States pharmacopeia and the relation of physicians thereto, This was primarily a book of standards, and its scope, by reason of that fact, was quite definitely fixed. It had never been a book of practical daily use to physicians, and there were difficulties in the way of its becoming such owing to the limitations of its scope. The practical value of this book to the general practitioner and student would further be increased if incompatibles could be mentioned in connection with each substance and preparation. To the same end the chemical tests of substances might possibly be curtailed. Among the needed improvements should be the omission therefrom of all obsolete drugs and those of slight value. The number of the preparations and of salts could be reduced with advantage.

Work of the Public Health Educational Committee.—Dr. Morton of New York told of what the women physicians of New York State had done in formulating plans for work in clubs, social settlements, and other places for the public good. She emphasized the importance of unity of purpose and the cooperation of effort. This work was being undertaken in many states of this country, and elsewhere. The object was to lessen suffering and to save life.

In Memoriam of Dr. Hamilton D. Wey of Elmira.—Dr. Henry L. Elsner delivered this memorial address.

Elements of Prognosis in Valvular Diseases of the Heart.—Dr. R. Abrahams of New York told of the inherent power of the heart to resist and moderate the effects of defective valves. Heredity and anemia had a great influence over prognosis in valvular diseases of the heart, especially in aortic insufficiency. Among the associated diseases which make a very serious prognosis in valvular disease he drew attention to pulmonary tuberculosis.

Dilatation of the Heart.—Dr. Wesley T. Mulligan of Rochester gave some case histories which were illustrative of dilatation of the heart due to various causes, together with their management. The most important changes in the muscle cells were granular, hyaline, and fatty degeneration. If the heart responds well when digitalis was given, the prognosis was favorable.

Dr. Allen A. Jones of Buffalo believed that anemia was a very important factor, especially in advanced years, in estimating the prognosis in valvular diseases of the heart. The condition of the myocardium was also all important in casting a prognosis, as well as what valves were involved. He believed that nervous strains long continued or frequently repeated was as important a cause of dilatation of the heart as physical strain.

The Clinical Significance of Subfebrile Temperature in Pulmonary Tuberculosis.—Dr. Arthur T. Laird of Albany read this paper. The normal temperature,

as well as the variations in health, was considered. With regard to subfebrile temperatures, there were other causes than tuberculosis. In tuberculosis the patients are very sensitive to all causes which tend to elevate the fever. If tuberculosis was suspected, the use of tuberculin and the *x-ray* would aid in substantiating the diagnosis. He emphasized the need for preventaria. A rise of the temperature, remaining high, not assignable to any complications indicates activity of the disease. He reported the histories of cases of pulmonary tuberculosis with long continued subfebrile temperatures. Subfebrile temperature, while not a pathogomonic symptom, was one of the cardinal symptoms of pulmonary tuberculosis.

A Contribution to the Study of Tremors.—Dr. M. NEUSTAEDTER of New York described the clinical and pathological features of the diseases associated with tremors. He also described a new method of obtaining a characteristic curve as an aid to diagnosis. A so-called "tremorgram" was recored upon a blackened recording drum, which revolved at medium speed. Dr. Neustaedter had made tremorgrams in 420 cases of diseases, some of which he presented. Among others tremorgrams were shown in dementia præcox, paralysis agitans, chorea, hysteria, etc. There was a difference between the tremors, and every form of tremor was distinctive of certain forms of disease.

Lumbar Puncture in General Practice.—Dr. NELSON G. RUSSELL of Albany read this paper. As a diagnostic and therapeutic agent no words were necessary. The technique of the procedure was described. He drew attention to the means of examination available in general practice and the practical application of the findings. The turbidity of the spinal fluid was usually due to the presence of cells. Illustrative cases were cited. In closing he argued for the more general use of lumbar puncture by the general practitioner when cerebrospinal disease was suspected.

Experimental Epidemic Poliomyelitis.—Drs. SIMON FLEXNER and PAUL A. LEWIS of New York gave an account of their experiments with epidemic poliomyelitis in monkeys. Their first efforts to transmit the disease to lower animals were made in 1907, at which time cerebrospinal fluid obtained by lumbar puncture was introduced into the spinal canal and peritoneal cavity in monkeys and in other animals. They were limited to this fluid because they did not secure material from a fatal case. The results were negative. Since September last they had had suitable material from two cases of poliomyelitis in human beings. The lumbar cord from one case and the entire spinal cord from another were used in these experiments. The gross and microscopic lesions were characteristic in both. The brain was chosen as the site of inoculation, which was made under ether anesthesia through small trephine openings. The injected material consisted of emulsions in salt solution of the spinal cord from the children and later of emulsions of the spinal cord of monkeys developing the disease. The microscopic study of the spinal cord of monkeys affected with the disease had shown without exception lesions similar to those of poliomyelitis in man. In some cases the lesions in the cords of monkeys could be detected with the naked eye. Up to the present time the two viruses had been carried successfully through eleven series of monkeys, and it was highly probable that the transmission could be carried on indefinitely. Not only was the spinal cord active but the cortex of the brain and other organs might also harbor the active virus. Not all monkeys developed the disease even when the inoculation was made into the brain. The virus of poliomyelitis was not difficult of transmission to monkeys as both specimens of spinal cord furnishing the original virus sufficed for the transmission of the disease successively. It could be stated definitely that it was not necessary that the virus be introduced into the brain, but that successive transmission was possible by way of the peritoneal cavity, by vascular injection, by subcutaneous injection, and by intraneural injection. There might be still other avenues for the entrance of the virus into the central nervous system. At the present time it would seem that it was more difficult to effect infection by way of the skin, the respiratory passages, and the digestive tract. Whatever the avenue of entrance traversed the virus became established in the spinal cord and medulla and set up characteristic lesions. Not all the monkeys which developed paralysis died; a certain number recovered in a large measure, but a residue of paralysis tended to remain which resembled the paralytic effects persisting in human beings. They had failed to discover bacteria either in film preparations or in cultures that could account for the disease. The viruses of vaccinia and rabies, neither of which had been certainly demonstrated in films or sections or cultivated artificially, withstood the action of glycerin, while bacteria withstood it far less well. Therefore, they used glycerinated virus from the spinal cords of monkeys affected with epidemic poliomyelitis with which they produced the disease in healthy monkeys. In order to determine whether this effect was due to the living virus or to an adherent toxic body the cord of these monkeys was injected into healthy monkeys, which latter developed paralysis after inoculation. The lesions in these monkeys were also characteristic. From a series of experiments undertaken to determine the probable size of the organism producing epidemic poliomyelitis, it appeared that the infecting agent of epidemic poliomyelitis belonged to the class of minute and filterable viruses that had not thus far been demonstrated with certainty under the microscope. The disease had been produced in a monkey by injecting an emulsion of the regional glands communicating with a nodule set up by a subcutaneous injection of the virus that had induced paralysis. Blood taken from a monkey at the height of the disease, defibrinated, and injected into the circulation of a healthy monkey was capable of causing the disease. The spinal cord from a human case of poliomyelitis retained its virulence when kept constantly frozen at 2° to 4° C. for a period of 40 days and also when kept for at least 50 days at a temperature of about 4° C. The spinal cord of a monkey still transmitted the disease after having been suspended for at least seven days over caustic potash in a dessicator. The virus had been cultivated in bouillon containing 10 per cent. rabbit's serum and also in a human ascitic fluid bouillon. None of the cultures contained bacteria that could be seen under the microscope, or cultivated in nutrient agar, and the dark field microscope showed no definite bodies. Experimental poliomyelitis in monkeys was a very severe disease, producing death in fully 40 per cent. of the inoculated animals that developed paralysis. They had reinoculated several of the recovered monkeys and had noted in some instances failure of the virus to act, while it caused paralysis in the control monkeys. They did not find that the course of an intracerebral inoculation could be modified by the simultaneous injection beneath the skin of a virus altered by heating to 55° to 57° C. for one hour or to 60° C. for one-half hour. Many guinea pigs and rabbits, one horse, two calves, three goats, three pigs, three sheep, six rats, six mice, six dogs, and four cats had had active virus introduced into the brain without causing any appreciable effect whatever. It might be possible that the nasopharynx bore the same relation to the spread of epidemic poliomyelitis as it did to epidemic cerebrospinal meningitis.

Adequacy of the Present-Day Treatment of Syphilis Tested by the Occurrence of Syphilitic Nervous Diseases.—Dr. JOSEPH COLLINS of New York said that certain nervous diseases, such as paresis, tabes, myelitis, pachymenin-

gitis, and endarteritis flowed out of syphilis oftentimes long after infection. Many of those patients in whom such diseases occurred had had what was taught to be adequate treatment for syphilis. The occurrence of them proved its inadequacy. Probably the chief reason why the syphilitic virus was not oftener negatived by treatment, and such nervous diseases prevented, was the widespread belief that iodide of potassium was an antisyphilitic agency. The utility of mercury in the treatment of syphilitic nervous disease offered proof that when properly administered mercury might be an adequate antisyphilitic. Dr. Collins said that the object of his communication was (1) to point out that the occurrence of nervous diseases that flowed out of syphilis indicated the fact that the present-day treatment of syphilis was inadequate; (2) that the teachings which promulgated the belief that such treatment was adequate were pernicious and far reaching in their injuriousness; and (3) that iodide of potassium was not in a strict sense an antisyphilitic agency in so much as it had not been shown to have a specific action upon the spirochete. In conclusion Dr. Collins said that he wished to state his opinion, which was based entirely upon his experience and the consideration which he had given to the disease and its sequela from a theoretical standpoint, that they should be able materially to diminish the occurrence of syphilitic nervous diseases by advocating the use of mercury as a specific for syphilis, and deprecating the use of iodide of potassium save as an absorbifacient of gummatous conditions. It was no part of his purpose to decry the therapeutic properties of the salts of iodine. He appreciated the therapeutic possibilities of iodine, but he was convinced that the therapy of organic disease, save gummatous formations, would be more satisfactory if the salts of iodine were no longer in use.

The Effects of Alcohol as Observed in Dermatology.—Dr. L. Duncan Bulkley of New York read this paper. Alcohol, he said, was a poison and when taken pure in sufficient quantities pretty promptly destroyed life. Experimentation had shown that alcohol was prejudicial to cell life, vegetable, and animal, with degenerative changes in almost all of the tissues of the body, and it was reasonable to expect that the skin was also affected. Experimentation had also shown that when animals were intoxicated with alcohol, they were more or less susceptible to bacterial infection, and resistant to experimental immunization. Chronic alcoholism produced a fatty metamorphosis in the cells of many organs, and degeneration in the nervous system; disturbances in the capillary circulation was a constant effect of alcohol. Alcohol was given off unoxidized by the kidneys, lungs, and skin. Alcohol circulated in the blood as such and profoundly affected metabolism. All these elements had a distinct bearing upon many affections of the skin not so much perhaps in their production as in their aggravation and continuance. Syphilis was always badly affected by alcohol and the latter was responsible for many of the evil results often seen in this disease, both in the skin and in the nervous system. The syphilitic should be an abstainer from alcohol from the moment of his infection. Acne constantly showed the effect of drinks containing alcohol, the condition varying more or less according to the character of the beverage. The acne rosacea of tipplers was well known, and this was often followed by a permanent dilatation of the capillaries of the face and hypertrophy of the nose, resulting even in rhinophyma. In beer and ale drinkers the eruption was of a more pustular character, often with large lesions. Eczema was often profoundly affected by alcoholic beverages, which might render the disease incurable while they were persisted in, even in moderation. Psoriasis was greatly aggravated by the indulgence in alcoholics and was caused to itch by such indulgences; the use of alcohol might also induce a fresh attack after a long period of freedom from the eruption. In cases of even moderate drinkers the disease yielded much more quickly under total abstinence. Dr. Bulkley also quoted illustrations from the literature of the injurious effects of alcohol in connection with diseased conditions of the skin and confirmed the references he gave by personal obesrvation, although particular cases were not cited for want of time. He treated of the value of alcohol externally in many diseased conditions of the skin, starting from its well-known importance in connection with aseptic and antiseptic surgery. He quoted many observers in regard to the beneficial effects of the alcohol preparations in the various inflammatory conditions, such as herpes, etc.

Joint Tuberculosis, with Special Reference to the Pathology and Treatment.—Dr. Leonard W. Ely of New York gave a description of some of the changes that he had observed in about sixty joints in the laboratory, together with conclusions drawn from a study of them. There were two types, (1) primary bony, and (2) primary synovial. Syphilitic joint disease possibly occurred but had not yet been proved. "Villous arteritis" was no pathological entity, but simply a symptom of chronic inflammation. Partial operations tended to aggravate the disease. The healing of tuberculous joints was usually by connective tissue formation. The general principles of treatment were almost always conservative in children, and radical in adults. Dr. Ely then described a new plan of operation, which was based upon the pathological findings and upon clinical experience, and which was applicable, especially to the hip and knee. It rested upon the principle of imitating nature and securing bony anchylosis in the joint without removing all the diseased tissue. Two cases of joint disease were cited in which this idea had been followed out.

Dr. Reginald H. Sayre of New York believed that incision was often a useful procedure in children with tuberculous joints, but was not always necessary. With rest and quiet many operations in such conditions would not be required. With the patient in good condition, with a temperature below 100° F., and with a good appetite, he believed it would be far better to leave these cases alone rather than to attempt any operative interference.

Dr. Ely said one should not give up the non-operative treatment of these cases until the viscera became involved. He reported one case of tuberculous synovitis which had existed for seven years. Then a little operation was performed and some tuberculous tabs were removed. This joint then started with the new growth, which required an exsection of that joint some two months later.

The Rheumatisms: Their Etiology and Pathology.—Dr. Egbert Le Fèvre of New York said that the term "rheumatic" was used to include many diseased conditions. He reviewed the theories regarding rheumatism and considered the infective theory and the experimental and clinical data to support the hypothesis. It was the general consensus of opinion that rheumatism was a microbic disease, as much so as pneumonia, typhoid or tuberculosis. Acute articular rheumatism was a disease of adolescence and early maturity. The action of the salicylates could only be explained by the supposition that they act either directly upon the microorganism or against the toxins of such an organism. The early recognition of this disease and the institution of systematic treatment was as important as in tuberculosis. The chronic forms of arthritis, classified under the head of rheumatism, presented great difficulties in study. He called attention to the classification of the chronic forms and the clinical types in relation to etiology.

Osteitis Deformans (Paget's Disease), with Report of Two Cases.—Dr. Henry L. Elsner of Syracuse read this paper. After going into the history and general considerations of the disease, he called attention to the

rare occurrence of it, and the resemblance to other bone changes. The clinical picture of the disease, as described by Paget, had not materially changed according to recent reports. Dr. Elsner reported the histories of two cases that came under his personal observation. The main features were the shortening of the patient in one case and an enormous enlargement of the right half of the calvarium. The right ilium was also greatly enlarged, as was the left clavicle and femur. There were no pressure symptoms. The second was a girl of seventeen years. She presented a characteristic appearance, as shown in the pictures. There was a peculiar broadening of the jaws, with an enlargement of the left parietal bone. The sternum, right clavicle and right ilium, were enlarged. There was an increase in length of the arm resembling in position and length the arm of an ape. The multiplicity of the bones involved was a constant characteristic. An interesting point in connection with these cases of osteitis deformans was the frequency of malignant growths as a complication. Eye changes, mostly of vascular character, were quite common. The luetic origin of this disease has been denied. The *x*-ray pictures justified the diagnosis.

Lantern-Slide Demonstration of X-Ray Pictures of Osteitis Deformans and Stomach and Intestinal Diseases.—Dr. Clarence E. Coon of Syracuse gave this demonstration.

(*To be continued.*)

NEW YORK ACADEMY OF MEDICINE.

SECTION ON MEDICINE.

Stated Meeting, Held December 21, 1909.

Dr. F. P. Solley in the Chair.

A Case of Pernicious Anemia.—Dr. George Reese Satterlee presented this case from the Washington Heights Hospital. The patient was a male, 67 years old, a painter by occupation, widowed. His family history was unimportant. He had not worked for three years. He ate and slept very irregularly, was constipated, had a good appetite as a rule, once drank coffee to excess, and was a moderate drinker. He gave an indefinite history of syphilis contracted forty years ago. He had all the diseases of childhood. He had also had yellow fever, typhoid fever, and malaria. He had three attacks of grippe and one of pneumonia. Following an attack of grippe one year ago he began to grow weak. About six weeks before his admission to the hospital he noticed a change in the color of his skin and a puffiness under the eyes, and recently edema of the feet. He was admitted to the hospital November 23, 1908. He was fairly well nourished and his musculature was lax. The skin was waxy, with a yellowish tint. The sclerae were yellowish. The pupils were small and reacted to light. The mucous membranes were pale. The tonsils were enlarged, and there were small petechiæ on the under surface of the tongue. The cervical, axillary, and inguinal lymph nodes were palpable. The liver and spleen were not palpable. The tibia was slightly tender to pressure. Edema of the feet was fairly well marked. There were no exaggerated reflexes. There was an atheroma of the right brachial artery more marked than of the left, and the blood pressure was lower on the right side. There was a loud and harsh apical systolic murmur. The pulmonic second sound was slightly accentuated. On November 26 colonic irrigations were given and repeated every day. On November 29 his general condition became much worse, and it seemed as if the patient would die. It was decided to give lecithin hypodermically, which was done in daily doses of 5 centigrams ampules for twelve days. After December 11 the patient failed rapidly, became edematous, had petechial hemorrhages in the skin, and blood in the urine and feces. There was also tenderness on pressure over the tibiæ. He had a very marked bronchitis. The spleen was just palpable; the liver was enlarged and tender. The microscopical examination of the red-blood cells showed quite a distinct destruction of their stroma, due to a hemolysis which was possibly caused by the administration of lecithin. On December 12 Fowler's solution of arsenic was given, 15 minims per day. The temperature was subnormal during this time. On December 15 the patient talked incoherently. On December 17 he had attacks of dyspnea lasting five minutes, for which oxygen was given; the red-blood cell count was 320,000, and hemoglobin 17 per cent., the lowest condition of the blood while the patient was under observation. On December 20 his condition was very much improved, and there was no more dyspnea; on the 27th his general condition had improved very much, and the edema of the feet was much less. After ten days of increasing doses of Fowler's solution the red-blood cell count had increased from 320,000 to 1,200,000. On December 28 the patient was given all the fresh air and light that was possible. From December 28 to the end of March he improved steadily under small daily doses of strychnine and Fowler's solution; he was then sent to the mountains for six months. The patient was again admitted to the hospital in the beginning of August of the same year. He had felt well up to a month previous, when he vomited, had diarrhea, was weak, had jaundice, and lost his appetite. He then presented much the same picture as on his previous admission, with marked intestinal distention and hemorrhagic petechiæ in the skin of the extremities. On August 7 he had diarrhea, with a few red-blood cells in the feces. On the 12th he was given Fowler's solution of arsenic, 30 minims daily, and strychnine. He had no appetite. On the 18th he had a very severe diarrhea, and undigested food and a few red-blood cells appeared in the feces. His temperature now rose for the first time, reaching 104.6° F. He was given bismuth subnitrate internally and opium and starch enemas. Fowler's solution was now stopped. On August 28 he again vomited and the red-blooded cells sank to 960,000 and the hemoglobin to 30 per cent. Fowler's solution and the strychine were stopped. His condition improved up to September 4, when diarrhea again became severe. On September 24 Fowler's solution was given, 42 minims a day. On September 30 colon irrigations were given, but in spite of this treatment his condition grew worse, and the red-blood cells decreased to 540,000 by October 6. A very severe bronchitis developed, which lasted two weeks. On October 28 it was decided to allow the patient to go to his home in the city, where he had been since, taking no medicine, but all the fresh air and good food possible. He had been under constant observation, and blood counts had been made every week, showing a rapid improvement until December 18, when the red-blood cells numbered 4,119,000 and the hemoglobin was 55 per cent. The patient was apparently a well man. His mentality was somewhat sluggish, but his grip was strong and he could walk as fast as the average man, and apart from a rather poor appetite, said he felt perfectly well. The blood picture, however, showed the undoubted characteristics of pernicious anemia. The whole course of this man's history showed how little effect medication had on the diseased condition itself, and showed that aside from careful nursing during the crises, fresh air, sunshine, and good food were the best "medicines." The interest in this case centered in the blood count. On November 30 the red cells numbered 1,200,000; leucocytes, 7,400; polymorphonuclears, 67 per cent.; lymphocytes, 28 per cent.; large mononuclears, 23 per cent.; eosinophiles 1 per cent.; basophiles, 1 per cent. The hemoglobin was 28 per cent., and there was a color index of 1.08. On December 19 the red-cell count was 320,000 and the hemoglobin was but 17 per cent. Improvement then followed. On January 4 the red-blood cells num-

bered 1,760,000 and the hemoglobin was 40 per cent. On February 27 the red cells numbered 4,000,000 and the hemoglobin was 82 per cent., with a color index of over 1. On March 15 the red cells numbered 3,500,000, the hemoglobin was 80 per cent., and the color index was plus 1. The patient then left the hospital and was away six months. On August 9 the red cells numbered 975,000 and the hemoglobin was 25 per cent., with an index of 0.8. On August 23 the red-blood cells numbered 1,170.000; on the 28th, 960,000, and the hemoglobin 30 per cent.; on August 31, the red-blood cells numbered 1,160,000 and the hemoglobin was 43 per cent. On September 4 the red cells had increased to 1,400,000 and the hemoglobin was 45 per cent. From then on the red-blood cells gradually diminished in number, and on September 17 a moderate number of nucleated red cells appeared after a long absence. On October 1 the cells numbered 890,000 and the hemoglobin was 40 per cent.; on October 6 the reds numbered 540,000 and there was 30 per cent. hemoglobin; on October 10 the reds numbered 700,000 and the hemoglobin was 32 per cent.; on October 19, just before the patient was discharged, the reds numbered 580,000 and there was 30 per cent. hemoglobin. A gradual improvement in his condition had been noted until December 11, when the red cells numbered 4,260,000, and on the 18th 4,119,000, with hemoglobin 55 per cent. and an index of 0.8. The leucocyte count was always low; there was a high percentage of lymphocytes. The urine never showed any large amounts of indican and rarely more than a trace of albumen and a few hyaline casts, but red-blood cells were nearly always present. The stools often contained red-blood cells and undigested food. Von Pirquet's cutaneous tuberculin reaction was negative.

Parasitology of Uncinariasis.—Dr. Francis Carter Wood presented a bottle containing hookworms and also some slides which showed male and female forms. They were American species. The interest in the question of hookworm disease that had developed during the last few years in this country was largely due to the discovery of its wide distribution, especially in the Southern States. Of course, it had been known for a long time that European tunnel workers and brick makers, as well as a large proportion of the population of Egypt, suffered from a peculiar chlorosis or anemia which was associated with this little parasite. This European worm was found to be adherent to the submucosa of the duodenum, and it was called *Ankylostoma duodenale,* or hookworm. There was no question but that the disease had been known for two or three hundred years, but only as a form of anemia. The parasites had only been recognized since 1843, and completely studied in the last few years. It was known that tunnel workers and brick makers were often afflicted with the disease, and then it was noticed also that coal miners suffered as well. Examination for the eggs of the parasites was made ten or fifteen years ago. Dr. Wood called attention to the suppression of the epidemic of hookworm disease in Porto Rico and to Mr. Rockefeller's munificence in giving one million dollars towards stamping out the disease in the South. There was no intermediate host. The parasite was readily distinguished by its morphology. The female was rather straight, while the male was more curved and had a broader caudal extremity. The differences between the two varieties of *Ankylostoma duodenale* had been well described by Dr. Stiles, and related chiefly to the small structures of the mouth portion. The European species had a series of hooks across the mouth; the American species had a small, round mouth with very small papillæ on edge. The eggs helped also in making a differentiation from the fact that in the European species the egg did not go beyond the stages of segmentation in the fresh stools; whereas in the American species they became completely segmented and might reach the embryonic stage. The eggs were oval and thin shelled, and contained four or eight cells. In the American species there were from 16 to 32 cells, or a larva might be present in the cell. The European eggs would not hatch until warmed; they then hatched in from 24 hours to 5 days, depending upon the air. The eggs of the American species, on the other hand, hatched rather rapidly. The differential diagnosis between the larvæ of *Uncinaria americana* and the larvæ of *Strongyloides intestinalis* was difficult, but it could usually be made by noting that the mouth of the uncinaria was long and narrow, while that of the strongyloides larva was broad. A further development of the parasite took place in the soil or fecal masses. If the feces were allowed to dry, or if mixed with charcoal and allowed to stand in a warm place, the parasites would grow, become larger, and crawl. With a pipette they then could be collected, examined, fixed, and even photographed. This was the rhabditiform stage in which the larvæ took food, grew, and shed their skin. But in this stage they were not infectious to man. The next or filariform stage, however, was the dangerous one to human beings. This occupied a period of from two, three, or five weeks. The probability was that both the American and European species had the same life history. The mode of infection was twofold. It was originally taught that hookworm disease was caused by swallowing water or by eating clay which contained the parasites; as was well known some people in the Southern States ate clay. This was what was termed the direct mouth infection. It was observed that the disease seemed to be connected with a peculiar skin eruption. This suggested that possibly the embryo might get in through the skin. Experimentally, it was soon shown to be a fact. Probably in a very large proportion of the cases of hookworm disease the parasites got in through the skin, especially the skin of the feet. In the warm climates, when the moisture was abundant there was a contamination of the feet with the soil which bore these larvæ. In such cases, of course, it was simple enough to check the disease by providing shoes. Embryos had been known to remain under the skin for four or five years. Not all the parasites got into the circulation. The parasite bored into the mucous membrane with the mouth end, which penetrated to the submucosa of the duodenum, and the animal was nourished by the epithelium as well as by the blood. There could not be any autoinfection. The parasites probably died out in time. Dr. Wood stated that he had seen as many as thirty-five or forty cases of hookworm disease during the past three or four years, all hospital or clinic cases.

A Case of Hookworm Infection Occurring in New York.—Dr. Harlow Brooks read this paper. (See page 191.)

Dr. Joseph F. Siler, Medical Corps, United States Army, said that recently it had been his good fortune to have a rather interesting experience with hookworm disease. Many Southern recruits passed through the recruiting depot at Fort Slocum, N. Y., at which point they were examined physically by medical officers. It had been noted that these men in general were somewhat below the average as to physique. An examination of stools in 124 recruits from the South had shown 109 cases of infection with *Necator Americanus.* These recruits were principally from North and South Carolina, Georgia, and Florida. Recruiting was done at different points throughout the country by officers of the cavalry, infantry, and artillery (laymen), and these recruiting officers rejected approximately 50 per cent. of the men who applied. The remaining 50 per cent. of applicants were forwarded to the recruiting depots for examination by medical officers, and as the recruits at Slocum were the better class of men and 85 per cent. of these men were infected, this high percentage was an index as to the widespread infection throughout the South. The infections at Slocum were mild in character;

only two men were rejected because of pronounced anemia. Major Chamberlain of the Medical Corps in examining recruits at Jackson Barracks, La., confirmed these findings, and brought out the fact that the parasite could live within the intestinal canal for at least three or four years. The percentage of infection at Slocum was somewhat high, but it was believed that in many rural sections of the South it was at least 50 per cent. The treatment at Fort Slocum was the routine one, with thymol, but this agent was used in larger doses than those referred to by Dr. Brooks. Fifteen grains were given every hour for four doses, and this treatment was repeated at the end of a week should stool examination still show ova. In regard to the question as to the use of alcohol with thymol, Manson referred to patients having been killed because of the use of alcohol during the administration of thymol. The routine treatment at Slocum was as follows: A dose of salts was given, which was followed by a limited diet; then 15 grains of thymol was given every hour for four doses; following this a saline was given if necessary. About 80 per cent. of the hookworms were expelled after the first treatment. It was usually necessary to repeat this treatment every week for at least a month to free the patient entirely of infection. In the *Journal of Tropical Medicine* were frequent references to another treatment which eliminated the toxic feature. This treatment consisted in the use of eucalyptus oil and castor oil given twice daily for a week or ten days. It was claimed that this treatment was practically as good as the thymol. It was interesting to note in the recent report to the surgeon-general of the army that while hookworm disease was prevalent among recruits, it had no particular bearing on the health of the army, as the chance of reinfection in army posts was practically *nil*.

Election of Officers.—*Chairman,* Dr. C. N. B. Camac; *Secretary,* Dr. H. S. Patterson.

State Medical Licensing Boards.

STATE BOARD EXAMINATION QUESTIONS.

West Virginia State Board of Health.

July 13, 14, *and* 15, 1909.

ANATOMY AND EMBRYOLOGY.

1. Give the general characteristics of a vertebra. Describe the atlas.
2. Describe the branches of the arch of the aorta.
3. Describe the course of the fibers in the optic commissure.
4. Name and describe the ducts of the liver.
5. Give origin and insertion of sartorius muscle; give function.
6. Give blood supply of leg, mentioning venous compensation.
7. Give foramen of exit of the cranial nerves.
8. Name muscles of deglutition.
9. Tell what you know of fetal development from the time of contact of the spermatozoon with the ovum during the first six weeks of development.
10. Describe the palmar arches and mention their surgical significance.

PHYSIOLOGY AND HISTOLOGY.

1. Give origin and functions of the bile.
2. Give functions of the liver.
3. Give the amount of saliva secreted in twenty-four hours in the adult; also give functions of the saliva.
4. Give the amount of blood (in pounds) in the body and state the functions of the red corpuscles.
5. Give the amount of water and solids in the body of a person weighing 145 pounds.
6. Name the organs of digestion in the order in which they belong.
7. Locate, describe, and give functions of the spleen.
8. Locate, describe, and give functions of the pancreas.
9. Describe a Peyer's patch and tell where it is found.
10. Describe a lobule of the liver.

CHEMISTRY AND MEDICAL JURISPRUDENCE.

1. What is an element, and how many are there?
2. Give chemical antidote for silver nitrate, mercury bichloride, tincture of iodine; what is formed?
3. Give Fehling's test for sugar. What is the chemical change as shown by reaction?
4. Would you treat burns with acids or alkalies, and why?
5. Define electrolysis.
6. Define oxidation; where does it occur in the body?
7. What are some of the certain signs of death?
8. Differentiate between dementia and hysteria.
9. Having visited a case, can the physician quit before its termination?
10. What are the legal requirements to practise medicine in West Virginia?

MATERIA MEDICA AND THERAPEUTICS.

1. Mention the therapeutic uses of ergot. Give the physiological action.
2. Name four coal-tar products used to reduce temperature; give dose of each.
3. Correct the following prescription:

   Atrophia sulphate, gr. i ss.
   Potassium iodid, 5ss.
   Infusa Digitalis, qs. ad. oz. ii.
   M-Sig. Teaspoonful in water four times daily.

4. Name four alkaloids of opium; give dose of each. Name three indications for their use. What is the effect of a full dose of opium on respiration?
5. How many grains of cocaine are contained in an ounce of a 20 per cent. solution? How many drops would you give an adult hypodermically?
6. Give dose of tincture of aconite root, tincture of digitalis, tincture of hyoscyamus (last edition of the Pharmacopœia). What active principles are found in each? Give dose.
7. State therapeutic uses of Pulvis jalapæ compositus and give composition.
8. Mention eight drugs the use of any one of which may cause skin eruptions.
9. Give the composition and the chief use of lotio hydrargyri nigra.
10. What are the therapeutic uses of ammonium muriaticum?

BACTERIOLOGY AND HYGIENE.

1. What is mixed infection? Illustrate.
2. Mention four of the most useful culture media. What should the reaction of a culture medium be?
3. Name the microorganism of erysipelas? What tissues does this microorganism chiefly effect?
4. Describe the method of staining sputum containing tubercle bacilli.
5. How do cells multiply?
6. Describe the modern system of ventilation.
7. What reasons can you give for not using personal clothing or toilet articles used by other people?
8. What diseases are known to be carried by animals and insects?
9. How would you manage a case of scarlet fever to prevent its spread, and what precautions would you take to avoid conveying it on your own clothing or person?
10. Give in detail the hygienic rules to be followed in every case of tuberculosis.

SURGERY.

1. What is inflammation? How does it extend? How does it terminate?
2. What is an abscess? Define acute and chronic abscess.
3. What is a carbuncle? Give treatment.
4. Define septicemia. Define pyemia.
5. Make a diagnosis between apoplexy, uremic coma, intoxication, and head injury.
6. What is lupus? Treatment?
7. Treatment of epistaxis?
8. Name and describe the different kinds of posture.
9. Describe and treat Colles's fracture.
10. What is orchitis? Treatment?

OBSTETRICS AND GYNECOLOGY.

1. In what way does the fetus receive its nourishment? Describe the placenta.
2. Cause, symptoms, and treatment of puerperal septicemia.
3. What are the dangers of a prolonged labor after the first stage is completed?
4. Menopause: What is it? Symptoms and treatment? Is it a physiological or pathological condition?

5. How long would you remain with patient after delivery, and why?
6. Explain the action of the abdominal muscles in labor.
7. What changes take place in the female at puberty?
8. How would you proceed in case of puerperal eclampsia? Cause?
9. Describe operation for perineal laceration. When and why should it be done?
10. Give early symptoms and treatment of cancer of the cervix uteri.

PRACTICE OF MEDICINE AND PEDIATRICS.

1. Give the cause and treatment of deficiency in excretion of urea.
2. Diagnose, treat, and give the cause of cholera infantum in an infant.
3. Etiology, symptoms, and treatment of acute lobar pneumonia.
4. Give the causes, symptoms, and treatment of Bright's disease.
5. Give the cause, symptoms, and treatment of hemiplegia in a person over sixty years of age.
6. Tonsillitis: Differentiate from diphtheria; give symptoms and treatment.
7. Intussusception: Define, diagnose, and treat.
8. Symptoms and treatment of empyema.
9. Give the etiology, pathology, duration, and treatment of typhoid fever.
10. Etiology, symptoms, and treatment of hysteria.

SPECIAL PRACTICE.

1. Give symptoms and diagnosis of chronic pleurisy with effusion.
2. Give symptoms and methods for early diagnosis of hip-joint disease.
3. Describe simple chronic laryngitis, giving diagnosis and treatment.
4. Diagnose and treat laryngeal diphtheria.
5. Give etiology, symptoms, diagnosis, and treatment of frontal sinus infection.
6. Diagnose and treat atrophic nasopharyngitis.
7. Describe the normal eye-ground as seen through the ophthalmoscope.
8. Describe eye conditions associated with chronic Bright's disease and diabetes mellitus.
9. Describe the normal knee-jerk. Give diagnostic significance of loss and exaggeration.
10. What is multiple neuritis? Give etiology and treatment.

ANSWERS TO STATE BOARD EXAMINATION QUESTIONS.

West Virginia State Board of Health.

July 13, 14, *and* 15, 1909.

ANATOMY AND EMBRYOLOGY.

1. The *general characters of a vertebra* are: Body or Centrum, and Neural arch. The latter consists of two pedicles, two laminæ, and seven processes (four articular, two transverse, and one spinous). For *atlas*, see Cunningham's "Anatomy" (1909), page 79; or Gray's "Anatomy" (1908), page 50.
2. See Cunningham's "Anatomy" (1909), page 800; or Gray's "Anatomy" (1908), page 595.
3. See Cunningham's "Anatomy" (1909), page 676; or Gray's "Anatomy" (1908), page 1038.
4. See Cunningham's "Anatomy" (1909), page 1118; or Gray's "Anatomy" (1908), page 1349.
5. *Origin:* Anterior superior spine of ilium and part of notch below. *Insertion:* Inner side of tibia near tubercle. *Function:* Flex leg on thigh, and thigh on pelvis; and rotate thigh outward.
6. See Cunningham's "Anatomy" (1909), pages 863 and 897; or Gray's "Anatomy" (1908), pages 707 and 756.
7. First through foramina in cribriform plate of ethmoid. Second, through optic foramen. Third, through sphenoidal fissure. Fourth, through sphenoidal fissure. Fifth, through sphenoidal fissure, foramen rotundum, and foramen ovale. Sixth, through sphenoidal fissure. Seventh, through stylomastoid foramen. Eighth, through internal auditory meatus. Ninth, tenth, and eleventh, through jugular foramen. Twelfth, through anterior condyloid foramen.
8. Hyoglossi, styloglossi, palatoglossi, palatopharyngei, azygos uvulæ, tensores palati, levatores palati, stylopharyngei, stylohyoids, geniohyoids, mylohyoids, thyrohyoids, digastrics, constrictors of the pharynx, and intrinsic muscles of tongue.
9. See Cunningham's "Anatomy" (1909), page 16; or Gray's "Anatomy" (1908), page 1559.
10. The *superficial palmar arch* is formed by the ulnar artery, and is completed by the ulnar artery anastomosing with a branch of the radial (superficial volar or princeps pollicis). It gives off the four digital branches. The surface marking is a line drawn transversely across the palm from a point where the web of the thumb joins the palm. The *deep palmar arch* is formed by the radial artery, and is completed by the radial artery anastomosing with a deep branch of the ulnar. Its branches are the palmar interosseous, perforating, and palmar recurrent arteries. The surface marking is a line drawn transversely across the palm, one-half inch nearer the wrist than the superficial arch. Wounds in this region are dangerous on account of the difficulty in checking the hemorrhage, and also on account of the important structures of the palm that may be damaged. In incision in the palm the line of these arteries should be avoided as far as possible.

PHYSIOLOGY AND HISTOLOGY.

1. The bile originates in the liver. The functions of the bile are: (1) To assist in the emulsification and saponification of fats; (2) to aid in the absorption of fats; (3) to stimulate the cells of the intestine to increased secretory activity, and so promote peristalsis, and at the same time tend to keep the feces moist; (4) to eliminate waste products of metabolism, such as lecithin and cholesterin; (5) it has a slight action in converting starch into sugar; (6) it neutralizes the acid chyme from the stomach, and thus inhibits peptic digestion; (7) it has a very feeble antiseptic action.
2. The functions of the liver are: (1) The secretion of bile; (2) the formation of glycogen; (3) the formation of urea and uric acid; (4) the manufacture of heat, and (5) the conversion of poisonous and harmful into inert material.
3. Probably from two and one-half to three pounds of saliva are secreted daily by an adult. *The functions of the saliva* are: (1) To moisten the mouth; (2) to assist in the solution of the soluble portions of the food, and thus (3) to administer to the sense of taste; (4) to lubricate the bolus of food, and thus (5) to facilitate the acts of mastication and deglutition, and (6) to change starches into dextrin and sugar.
4. The blood is about one-thirteenth of the body weight. The function of the red corpuscles is to carry oxygen to the tissues.
5. Water being about two-thirds and solids one-third, there will be about 97 pounds water and 48 pounds solids.
6. Mouth (with tongue, teeth, and salivary glands), pharynx, esophagus, stomach, small intestine (duodenum, jejunum, ileum), large intestsine (cecum, ascending colon, transverse colon, descending colon, sigmoid flexure, and rectum), with liver and pancreas.
7. The *function of the spleen:* The following theories have been held: (1) It is a source of production of the white blood corpuscles; (2) it is a source of production of the red blood corpuscles during fetal life; (3) it is a place where the red blood corpuscles are destroyed; (4) uric acid is produced in the spleen; (5) an enzyme is produced in the spleen and is carried by the blood to the pancreas, where it converts the trypsinogen into trypsin. For location and description, see Cunningham's "Anatomy" (1909), page 1210; or Gray's "Anatomy" (1908), page 1361.
8. The *functions of the pancreas* are: (*a*) The secretion of the pancreatic juice, which (1) changes proteids into proteoses and peptones, and afterward decomposes them into leucin and tyrosin; (2) converts starch into maltose; (3) emulsifies and saponifies fats, and (4) causes milk to curdle. (*b*) The manufacture of an internal secretion. For location and description, see Cunningham's "Anatomy" (1909), page 1124; or Gray's "Anatomy" (1908), page 1355.
9. See Cunningham's "Anatomy" (1909), page 1064; or Gray's "Anatomy" (1908), page 1304.
10. A lobule of the liver is about 1-20 to 1-12 inch in diameter. It has a darkish red center and a lighter circumference. The center is occupied by an intralobular vein which collects the blood from the capillaries of the lobule, and flows into the sublobular vein, which latter opens into the hepatic vein. Around the lobules are the interlobular veins; these are branches of the portal system; capillaries passing from the circumference to the center of the lobule connect the interlobular and intralobular veins. Between the network of capillaries in the lobule the heptaic cells are packed.

CHEMISTRY AND MEDICAL JURISPRUDENCE.

1. An *element* is a substance which cannot, by any known

means, be split up into two or more other kinds of substance. There are 80 or 81 elements.

2. (1) For silver nitrate, sodium chloride; (2) for mercury bichloride, white of egg; (3) for tincture of iodine, no chemical antidote; but starch is given. There are formed (1) silver chloride, (2) mercury albuminate, (3) a blue color.

3. *Fehling's test:* Place in a test-tube a few c.c. of the liquid prepared as stated below, and boil; no reddish tinge should be observable, even after five minutes' repose. Add the liquid under examination gradually, and boil after each addition. In the presence of sugar a yellow or red precipitate is formed. In the presence of *traces* of glucose, only a small amount of precipitate is produced, which adheres to the glass, and is best seen when the blue liquid is poured out. [The reagent must be kept in two solutions, which are to be mixed immediately before use. Solution I consists of 34.653 gms. of crystallized $CuSO_4$, dissolved in water to 500 c.c., and solution II of 130 gms. of Rochelle salt dissolved to 500 c.c. in NaHO solution of sp. gr. 1.12. When required for use equal volumes of the two solutions are mixed, and the mixture diluted with four volumes of water.] The copper sulphate is reduced to copper oxide.

5. *Electrolysis* is the process of electrical conduction accompanied by the separation of the constituents of the electrolyte or the decomposition of a chemical compound by passing an electric current through it.

6. By *oxidation* is meant the act of union of oxygen with another element or compound. It occurs in all (or nearly all) the tissues of the body, chiefly in the lungs.

7. The complete and permanent cessation of respiration and circulation, rigor mortis, loss of body heat, pallor of the body, putrefaction.

8. *Dementia* is a condition of mental enfeeblement which gradually increases until absolute mental decay ensues. *Hysteria* is a morbid condition of the nervous system which may show every variety of nervous system due to deranged function of the cerebral and spinal centers, and associated with lowered will power and exaggerated emotional tendencies.

9. Yes; a physician can quit, provided he gives ample notice of his intention, so that the patient can obtain the services of another physician.

10. Graduation from a reputable medical college, recognized as such by the State Board of Health, and a certificate giving license to practise, issued by the said State Board of Health.

MATERIA MEDICA AND THERAPEUTICS.

1. Ergot. *Therapeutic uses:* To promote uterine contractions during third stage of labor; fibroids, menorrhagia, postpartum hemorrhage. Some forms of amenorrhea and dysmenorrhea, dysentery, arterial hemorrhage, congestive headaches, laxity of sphincters, of bladder or rectum, hemorrhoids, aneurysm, diabetes, urinary incontinence, direct paralysis of the sphincter vesicæ, atonic spermatorrhea. *Physiological action:* Ergot stimulates and causes contraction of involuntary muscle fibers, hence it is a vasoconstrictor, hemostatic, and oxytocic. It is also a cardiac sedative; it raises the blood pressure, it increases peristalsis, and is an emmenagogue.

2. Acetanilide, gr. iv; antipyrin, gr. iv; phenacetin, gr. viijss; exalgin, gr. ij.

3. ℞ Atropinæ sulphatis, gr. 1/6.
Potassii iodide, ʒss.
Infusi digitalis q. s. ad ʒij. M.
Sig: One teaspoonful in water four times a day.

4. Morphine, gr. 1/5; codeine, gr. 1/2; narcotine (hydrochlorid), gr. v; the other alkaloids are not used medicinally. *Indications:* To relieve pain; to produce sleep; to alloy irritation. Respiration is slowed.

5. Ninety-six grains. About one and a half minims; but I would not use a 20 per cent. solution.

6.

TINCTURE OF	DOSE	ACTIVE PRINCIPLES	DOSE
Aconite.	♏x.	Aconitine.	gr. 1/400.
Digitalis.	♏xv.	Digitalin.	gr. 1/150.
		Digitalein.	gr. 1/100.
		Digitin.	.....
		Digitonin.	gr. 1/200
		Digitoxin.	gr. 1/150.
Hyoscyamus.	♏xv.	Hyoscyamine.	gr. 1/128.
		Hyoscine.	gr. 1/128.

7. As a hydragogue purge, in dropsy and cerebral congestion. It is composed of 35 parts of jalap and 65 parts of potassium bitartrate.

8. Belladonna, quinine, bromides, chloral, copeiba, cubebs, morphine, mercury.

9. It is made by adding one dram of calomel to a pint of lime water. It is chiefly used as a wash for syphilitic sores.

10. It stimulates the respiratory mucous membranes, and so is used in bronchitis and pneumonia; also in torpid and other liver conditions and ovarian neuralgia.

BACTERIOLOGY AND HYGIENE.

1. A mixed infection is one in which more than one kind of microorganism is present—as *tetanus bacillus*, which thrives in the presence of saprophytic organisms which absorb the oxygen.

2. Gelatin, agar, blood-serum, bouillon. The reaction should be faintly alkaline or neutral.

3. *Streptococcus erysipelatis:* It chiefly affects the skin and connective tissues (lymph spaces and cellular tissues).

4. The sputum must be recent, free from particles of food or other foreign matter; select a cheesy-looking nodule and smear it on a slide, making the smear as thin as possible. Then cover it with some carbolfuchsin and let it steam over a small flame for about two minutes, care being taken that it does not boil. Wash it thoroughly in water and then decolorize by immersing it in a solution of any dilute mineral acid for about a minute. Then make a contrast stain with solution of Loeffler's methylene blue for about a minute; wash it again and examine with oil immersion lens. The tubercle bacilli will appear as thin red rods, while all other bacteria will appear blue.

5. Cells multiply by: (1) Amitosis, and (2) karyokinesis.

6. "In the *plenum* system the air is drawn into a box, in which the revolving blades of a fan are located, and it is then driven into a central conduit and from there through appropriate shafts to the spaces for which it is intended. In the *vacuum* system the air is extracted from the various rooms through pipes leading to a central shaft, where it is drawn into the fan and discharged outwardly."

7. (1) It is a dirty habit; (2) it is also a dangerous habit, as disease may be conveyed in this way.

8. Malaria, yellow fever, filariasis, bubonic plague, typhoid, cholera, leprosy, tuberculosis, smallpox, ringworm, sleeping-sickness, hook-worm disease, diphtheria, measles, scarlet fever, pneumonia, intestinal parasites, glanders, echinococcus, anthrax, rabies.

9. Complete isolation and quarantine, followed by rigid disinfection; special care must be taken during period of desquamation. On entering the room the physician should put on a sterilized gown over his clothes, and leave the gown behind him when he leaves; he should also wash his hands with a disinfectant.

10. "The patient's quarters should be free from dust, and admit of spending many hours daily in the open air in all weathers, properly sheltered, and, if very ill, lying wrapped in a hammock or reclining chair. His bedroom should be well aired at night, draughts being avoided. The room should be uncarpeted and free from hangings. It should be often cleaned and periodically disinfected. All sputum should be collected in paper spit-cups, which should be burned daily. Smoking should be forbidden. Harm is done by any exercise which results in fatigue, and while fever exists it should not be attempted at all. Patients should be taught the necessity of practising lung gymnastics and breathing only through the nose, which should be kept clear and free from occlusion by secretions, or an hypertrophied catarrhal mucosa. . . . The clothing should be woolen, but not too heavy, or sweating is increased; and a flannel nightgown and loosely knit leggings should be worn at night in cool weather. The skin should be cleansed by daily sponge-baths of lukewarm alcohol and water."

SURGERY.

1. *Inflammation* is the succession of changes which occur in a part as the result of some kind of injury, provided that this injury is not sufficient to immediately destroy the vitality of the part. It extends by the blood vessels, lymphatics, and continuity of tissue. It terminates in return of the tissues to health (by resolution or organization or new growth), or by death of tissue (by suppuration, ulceration, or gangrene).

2. An abscess is a circumscribed collection of a pus in a cavity of new formation. Acute abscesses are marked by inflammatory symptoms, pain, and heat, and by rapid development; chronic abscesses, by the absence of pain and heat, and by their sluggish course.

3. A carbuncle is a localized inflammation of the subcutaneous tissue, with fibrinous exudation and multiple necrotic foci. *Treatment:* Tonics, stimulants, good diet,

free, crucial incisions with curetting of the sloughs, and swabbing with pure carbolic acid.

4. *Septicemia* is a condition due to microorganisms multiplying in the blood, and is characterized by high temperature, but not relieved by getting rid of the original source of infection. *Pyemia* is due to particles of blood clot carrying microorganisms to parts distant from the original source and there setting up metastatic abscesses.

5.

COMA FROM INTRACRANIAL INJURY	APOPLECTIC COMA	UREMIC COMA	ALCOHOLIC COMA
Deep coma; may have history of onset after fall or injury. Evidence of fracture of vertex or base.	Deep coma; sudden onset. If any injury, only a scalp wound.	Deep coma. Slow onset, unless convulsions have preceded the coma.	Can be aroused by supraorbital pressure unless very profound.
Pupil dilated on side of lesion. Choked disc.	Pupils unequal or dilated. Contracted in hemorrhage into the pons.	Albuminuric retinitis.	Pupils normal or somewhat dilated.
Pulse very slow.	Pulse full and slow, often arteriosclerotic, high-tension pulse.	Pulse rapid.	Pulse more rapid than normal and full.
Respiration slow and stertorous.	Respiration slow and irregular.	Respiration frequent and irregular.	Regular respiration.
Temperature higher—101°.	Temperature higher on paralyzed side, but lower in rectum.		May be low or normal.
Urine normal or contains trace of albumin.	Urine contains trace of albumin, but may be same as in uremia.	Urine shows albumin, casts, and low urea percentage.	Normal.
Hemiplegia on opposite side to that of injury. If contusion of brain is also present, may have generalized convulsions.	Hemiplegia with convulsions on one side.		

6. *Lupus vulgaris* is a tuberculous infection of the skin; it is generally found upon the face, particularly the nose and cheeks. It begins as pinkish nodule which is painless, and spreads to other nodules, and generally ends in ulceration, with destruction of mucous membrane or cartilage.

Treatment: In the early stages the small nodule may be excised. If not seen till later, curettage with a sharp spoon, followed by cauterization with pure carbolic acid, has been recommended. This can be repeated at intervals of three or four weeks, if necessary. Finsen light and tuberculin have also been used.

7. *To arrest epistaxis:* (1) Try to cauterize the bleeding point; (2) plug the nasal cavity with gauze soaked in adrenalin; (3) inject into the nares a solution of peroxide of hydrogen; (4) plugging the nares, anteriorly and posteriorly; (5) an inflating plug may be used.

8. Postures. *Dorsal,* one in which the patient lies on the back; *knee-chest, or genupectoral,* one in which the patient rests upon the knees and chest, the arms being crossed above the head; *knee-elbow, or genucubital,* one in which the patient lies upon the knees and elbows, the head resting upon the hands; *lithotomy,* one in which the patient lies on the back with the legs flexed on the thighs, and the thighs flexed on the abdomen and abducted; *Sim's,* one in which the patient lies on the left side, with the right knee and thigh drawn up and the left arm placed along the back; the chest is inclined forward so that the patient rests upon it; *Edebahl's,* one in which the patient lies on the back, with the legs flexed on the thighs and the thighs on the abdomen, the hips being elevated and the thigh strongly abducted; *Trendelenburg's,* one in which the patient lies on the back, on a plane inclined about 45°, the feet and legs hanging over the end of the table.

9. *Colles' fracture* is a fracture of the lower end of the radius; it is generally transverse, and is usually within an inch or an inch and a half of the articular surface. There is a characteristic deformity caused by the lower fragment, and the carpus forming a prominence on the dorsal surface; at the same time there is a projection on the palmar surface just above the wrist, caused by the upper fragment. The hand is abducted and pronated, and the styloid process of the ulna becomes very prominent. It is generally caused by a fall on the outstretched palm. For *treatment,* see Rose and Carless' "Surgery" (1908), page 522; or DeCosta's "Surgery" (1908), page 507.

10. *Orchitis* is inflammation of the testicle. *Treatment:* Rest in bed; elevation of the parts; hot or cold applications; pain is to be relieved by opiates or leeches; lead water and laudanum should be applied; salines or cathartics are to be administered. Sometimes strapping the testicle is of service; so, too, is the application of ichthyol and lanolin.

OBSTETRICS AND GYNECOLOGY.

1. *Nutrition of fetus:* "(1) At first the ovum absorbs nutriment simply through the vitelline membrane, while passing through the Fallopian tube. The nutrient material is supplied by the secretion of the tube itself, or may consist in part of seminal fluid introduced from without. (2) The vitellus is absorbed by the entoderm lining the umbilical vesicle and alimentary canal, and later it is absorbed and conveyed into the body of the embryo by the blood-vessels of the area vasculosa. (3) When the contents of the umbilical vesicle are exhausted the chorial villi appear and take up nourishment from the uterine decidua, with which they are in contact. (4) With the disappearance of villi in the chorion leve, the villi of the decidual serotina develop into the placenta, where they take up nutriment from the maternal blood with which they are surrounded."

At full term the *placenta* is a soft, spongy mass, roughly saucer-shaped, from six to nine inches in diameter, about three-quarters of an inch in thickness at the central point, and weighs about one pound.

2. See Williams' "Obstetrics" (1909), page 852; or Hirst's "Obstetrics" (1909), page 764.

3. Asphyxiation of fetus; inspiration-pneumonia of fetus; death or exhaustion of mother; pressure necrosis formation of fistulæ; sepsis; and post-partum hemorrhage.

4. *Menopause* is the period when menstruation ceases; it usually occurs between the fortieth and fiftieth years; it is attended by disturbances of digestion, flashes of heat, nervous troubles; treatment is symptomatic, dietetic, and hygienic. It is a physiological condition normally, but may become pathological.

5. At least one hour; longer if necessary; for fear of post-partum hemorrhage; the uterine contraction should be good and the pulse below 100 before the physician leaves.

6. See Williams' "Obstetrics" (1909), page 286; or Hirst's "Obstetrics" (1909), page 333.

7. Development of the reproductive organs, enlargement of the breast, hair on pubis and axilla; the form becomes rounded, the hips widen, menstruation occurs; there are certain mental and emotional changes, and "the development of those womanly beauties physiologically designed to attract the male."

8. Puerperal eclampsia. *Preventive treatment:* (1) The amount of nitrogenous food should be diminished to a minimum; (2) the production and absorption of poisonous materials in the intestines and body tissues should be limited and their elimination should be aided by improving the action of the bowels, the kidneys, the liver, the skin, and the lungs; (3) the source of the fetal metabolic products and the peripheral irritation in the uterus should, if necessary, be removed by evacuating that organ. *Curative treatment:* (1) Controlling the convulsions (by chloroform, veratrum, or chloral); (2) elimination of the poison or poisons which are presumed to cause the convulsions; (3) emptying the uterus under deep anesthesia, by some method that is rapid and that will cause as little injury to the woman as possible. The *causes* may be: Uremia, albuminuria, imperfect elimination of carbon dioxide by the lungs, medicinal poisons, septic infection; predisposing causes are

renal disease and imperfect elimination by the skin, bowels, and kidneys.

9. See Williams' "Obstetrics" (1909), page 325; or Hirst's "Obstetrics" (1909), pages 609 and 868.

10. CANCER OF THE CERVIX. *Early symptoms:* Pain, hemorrhage, offensive discharge, wasting; the cervix is enlarged and breaks down. *Treatment:* Removal of the uterus.

PRACTICE OF MEDICINE AND PEDIATRICS.

1. *Causes:* Carcinoma, cirrhosis of liver, acute febrile jaundice, nephritis, Addison's disease, lead poisoning. *Treatment:* Purgatives (elatorium, calomel, compound jolap powder), hot bath, amylnitrite, liquid diet. And see answer to OBSTETRICS, 8.

2. See French's "Practice" (1907), page 782; or Osler's "Practice" (1909), page 507.

3. See French's "Practice" (1907), page 151; or Osler's "Practice" (1909), page 165.

4. See French's "Practice" (1907), page 892; or Osler's "Practice" (1909), page 686.

5. See French's "Practice" (1907), page 1071; or Osler's "Practice" (1909), page 966.

6. In *diphtheria* the onset is more gradual; the temperature rises to about 101° to 103° F.; the tonsils are not much enlarged; there is an exudate of a thick, grayish membrane which is very adherent, is removed only with difficulty, and leaves a bleeding surface; this membrane soon reforms and may be found on the fauces and pharynx as well as on the tonsils; in the exudate the Klebs-Loeffler bacilli may be found. In *fallicular tonsillitis* the onset is more sudden; the temperature may be a little higher than that of diphtheria; there is no membrane, but the tonsils are read and swollen, and in the crypts are seen white, cheesy spots or plugs, which consist of broken-down epithelium, and are easily brushed away; Klebs-Loeffler bacilli are never found. See French's "Practice" (1907), page 719; or Osler's "Practice" (1909), page 445.

7.

STRANGULATION	INTUSSUSCEPTION.	TWISTS (VOLVULUS)
Subjective Symptoms.	*Subjective Symptoms.*	*Subjective Symptoms.*
1. Generally occurs after age of 20.	1. Most frequent in childhood.	1. Most frequent after age of 30.
2. Pain localized, rapid collapse.	2. Constant tenesmus.	2. Pain diffuse.
3. Pain intense, paroxysmal in character.	3. Pain develops suddenly and is continuous.	3. Pain paroxysmal; recurs less often than in strangulation.
4. Constipation complete.	4. Frequent diarrhea, passage of bloody mucous.	4. Constipation complete.
Objective Symptoms.	*Objective Symptoms.*	*Objective Symptoms.*
1. Temperature often subnormal.	1. Temperature normal or subnormal.	1. Temperature slightly elevated.
2. Pulse very weak.	2. Same as in strangulation.	2. Same as in strangulation.
3. Stercoraceous vomiting comes on early.	3. Same as in strangulation.	3. Same as in strangulation.
4. Location in small intestine.	4. Localization in small intestine; bowel frequently protrudes at rectum.	4. Location, small intestine; abdomen often protrudes, in certain areas, giving dullness on percussion.

—See French's "Practice" (1907), page 799; or Osler's "Practice" (1909), page 519.

8. EMPYEMA. *Symptoms:* High and irregular fever, sweats, chill, diminished breath sounds and vocal femitus, impaired mobility of chest, dullness on affected side, heart displaced to opposite side, leucocytosis. Absolute diagnosis is made by aspiration, showing the fluid to be pus. *Treatment:* Aspiration, drainage, irrigation, resection of ribs (Estlander's operation), or resection of chest wall (Schede's operation).

9. See French's "Practice" (1907), page 65; or Osler's "Practice" (1909), page 57.

10. See French's "Practice" (1907), page 1140; or Osler's "Practice" (1909), page 1076.

SPECIAL PRACTICE.

1. See French's "Practice" (1907), page 701; or Osler's "Practice" (1909), page 655.

2. *The early symptoms of hip-joint disease* are: Night cries (in a child); lameness in the morning; a slight limp; tendency to become tired on slight exertion; wasting; spasm; pain; swelling; and deformity (either real or apparent).

3. Simple chronic laryngitis may follow an acute attack, and be due to the same causes. *The symptoms* are tickling in the throat, hoarseness, persistent cough, and thick, tenacious, mucoid expectoration. Physical examination reveals congestion and granulations on the mucous membrane. *The general treatment* is largely dietetic, stimulant, and hygienic. The local treatment consists in removing erosions or enlarged follicles under cocaine by means of silver nitrate or the galvanocautery, and the use of stimulating inhalations and applications. Silver nitrate (gr. 10-20 to ℥i), glycerite of tannin, or boroglycerid (50 per cent.) may be used as application. Alkaline sprays and nasal douches may be employed. Guaiac may be administered in lozenge form.

4. See French's "Practice" (1907), page 188; or Osler's "Practice" (1909), page 202.

5. FRONTAL SINUS INFECTION. *Etiology:* Extension from ethmoid cells, or obstruction of the nasofrontal duct; or hypertrophic inflammation of the mucosa or growths within the nose. *Symptoms and diagnosis:* Throbbing pain in frontal cells, discharge of offensive mucopurulent pus from one or both sides; transillumination will be diminished on the affected side. *Treatment* consists in laying open the cavity, through an incision along the inner part of the eyebrow, and trephining. The wall is curetted, the infundibulum enlarged, and a drainage tube left in it for two or three days. The cavity is then washed out daily through the nose till all discharge has ceased.

6. ATROPHIC NASOPHARYNGITIS. *Symptams:* Characteristic burning, itching sensation, and an extremely dry feeling in the throat. There is usually a dry hacking cough, very little expectoration except what accumulates in the post-nasal space, and is removed by hawking it up. The secretions of the glands are changed in quality; they become thick and tend to stick to the pharynx, forming dry crusts and scabs which are very hard to remove. The membrane may look dry, parched, and glazed, with here and there a nodular condition. If the secretions are examined, a great variety of bacteria may be found. *Treatment:* Remove any constitutional causes as quickly as possible. Get the general health into good condition, and keep the parts thoroughly clean with a gargle or spray. If there are any congested spots, correct these by applications of nitrate of silver. Give cathartics if necessary, and attend to the digestive tract and to the hygienic surroundings.

7. "In carrying out a complete examination of the fundus the two landmarks which should be first found are the optic nerve and the macula (yellow spot). The former appears as an oval pinkish-white disk. A pit with sloping sides is in the center (physiological excavation), with the mottled appearance of the lamina cribrosa at its bottom. A white ring of varying breadth (scleral ring) surrounds the disk, and outside of this more or less pigment (choroidal ring). From the nerve comes the central artery of the retina as a single trunk, or already divided, and it then divides and subdivides on the retina. The veins follow in general the same course as the arteries. The color, amount of blood supply, sharpness of outline, and swelling of the disk should not escape notice. The presence of an excavation with sharp sides, over which the vessels seem to fall (cupped disk), may denote glaucoma. The other landmark—the macula—which is very difficult to see when the pupil is small, is an area of deeper color than the surrounding fundus, and shows a pit in its center with a bright reflex (fovea centralis). The retinal vessels should be followed from the nerve over the fundus and changes in them noted. The general appearance of the fundus is variable with the amount of pigment, depending on the complexion of the individual."

8. In *chronic Bright's disease* there may be albuminuric retinitis, with serious swelling of the disk and surrounding retina, hemorrhagic extravasations, dilatation of capillaries and veins, with fatty or hyaline degeneration of the vessel walls. In *diabetes mellitus* the vessels of the retina may be dilated, the retina may atrophy, the fundus is light yellow in color; amblyopia, presbyopia, and loss of accommodation may occur.

9. When the thigh is supported and the leg flexed at the

knee, a tap on the tendon just below the patella causes the leg to be suddenly extended. It is *lost* in locomotor ataxia, transverse myelitis, poliomyelitis, peripheral neuritis, spinal meningitis, epilepsy, and chorea. It is *exaggerated* in apoplexy, sclerosis, paraplegia, unilateral lesions of spinal cord, tetanus, cerebellar ataxia.

10. MULTIPLE NEURITIS is a neuritis (inflammation of bundles of nerve fibers) in which several nerves are involved. *Etiology:* Poisons of infectious diseases, or organic or mineral poisons, cachectic conditions, exposure to cold, overexertion. *Treatment:* Rest in bed, morphine or hot applications, strychnine, arsenic, and heat (and remove) the cause.

Books Received.

The MEDICAL RECORD *is pleased to receive all new publications which may be sent to it, and an acknowledgment will promptly be made of their receipt under this heading, but it must be with the distinct understanding that it is under no obligation to notice or review any publication received by it which in the judgment of its editor will not be of interest to its readers.*

Varicella	168	—
Typhoid Fever	39	5
Whooping Cough	28	6
Cerebrospinal Meningitis	4	12
Malarial Fever	—	—
Totals	2,898	279

Typhobacillosis of Landouzy and Rare Late Localization of Acute Tuberculous Infection in the Child.—E. Weill and G. Mouriquand describe the type of tuberculous infection that was termed by Landouzy typhobacillosis, in which the early general symptoms are like those of typhoid, the fever corresponding at first to the typhoid curve, but in which the rose spots do not appear and the Widal reaction is negative. In such cases the pulse curve is independent of the temperature. The temperature becomes oscillating and irregular, finally emaciation and weakness become extreme in spite of a great appetite, and at last lesions develop in the lungs, peritoneum, or meninges. The temperature is not always high. A pleurisy frequently is the first lung sign. The prognosis of such cases is bad from the first on account of the location of the lesions. The author gives illustrative cases of all the different types of these late lesions.—*La Presse Médicole.*

Health Reports.—The following cases of and deaths from smallpox, yellow fever, cholera, and plague have been reported to the Surgeon-General, Public Health and Marine-Hospital Service, during the week ended January 21, 1910:

		Cases.	Deaths.

THE PATHOLOGICAL PRODROMES OF TABOPARESIS.*

SYPHILIS; MENINGITIS; THE GENESIS OF THE CRANIAL NERVE IMPLICATIONS.

By TOM A. WILLIAMS, M.B., C.M. (Edin.)

WASHINGTON, D. C.

ONE of the main contentions against the ideas of Nageotte as to the pathogenesis of tabes dorsalis has been the supposed unessentialness of the chronic meningitis he invoked as the necessary antecedent of locomotor ataxia. As to his 11 cases all showing marked meningeal exudates, the objection is made that they were really exceptions; for other observers had failed to find lesions in the meninges. Nageotte believed that an incomplete examination was the cause of this; but, in turn, it was objected that if his theory were correct, meningeal inflammation should have been found around the cranial nerves, which are so often implicated symptomatically early in tabetics.

Very few of Nageotte's opponents go so far as to deny that persistent lymphocytosis really indicates meningitis; and it is pretty generally conceded to be pathognomonic of meningeal irritation at least. We need not quarrel about terms, for the commencement of the inflammatory process may be designated by the term irritation; hence the difficulty is merely one of stage, measured by degree. Moreover, the appearance revealed under the microscope, after the death of the patient who has shown persistent lymphocytosis, of considerable meningeal infiltration with small round cells as well as with commencing and even complete organization of chronic inflammation proves that lymphocytosis does not occur by a mere multiplication in the blood of the white cells, as in leukemia.

I am now speaking of the abundant lymphocytoses so characteristic of syphilis. The lymphocytosis sometimes found during mumps and even that occurring so often in herpes zoster are less abundant and disappear quite rapidly. For the purpose of this discussion, we are dealing only with such marked exudates as almost crowd the field; that is to say, occurring in blocks or chains, and indicative of severe meningeal reaction. Hence the demonstration does not depend upon the refined and difficult laboratory methods, and is within the reach of any practitioner.

*Through the kindness of Dr. Clovis Vincent, the writer is enabled to place before American readers the results of an investigation Dr. Vincent has been pursuing during the last five years in the clinics of the Parisian Hospitals La Pitié, La Salpétrière, and St. Louis, and in the laboratories of Babinski and Nageotte, Raymond, and Chauffard. The reader will see that the results of Dr. Vincent's research afford still further corroboration of the ideas so long held by Babinski and Nageotte that all the symptoms of taboparesis ensue upon a chronic meningitis of syphilitic nature. The data here expounded clearly show the untenability of the dystrophic theory of taboparesis.

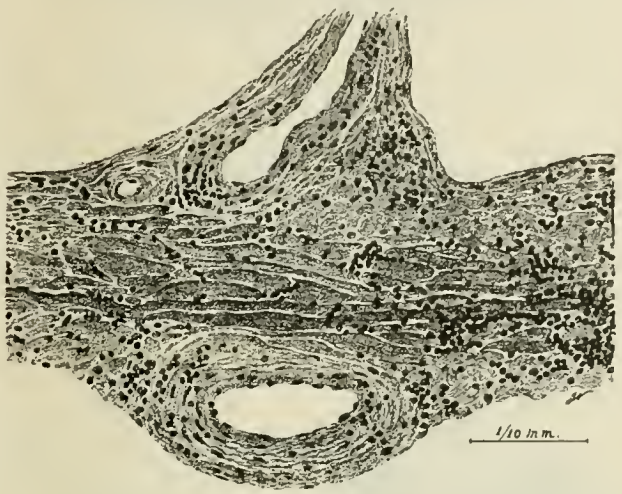

FIG. 1.—Showing the type of meningitis in taboparesis. It shows the pia mater over the posterior region of the spinal cord at a dorsal segment magnified 205 diameters and stained with haematoxyline and eosine. Note thickened connective tissue and the infiltration of lymphocytes and epithelioid cells; also a thickened blood vessel entering the spinal cord along a septum. (From Nageotte.)

The cells in the syphilitic meningitis differ also in kind, being surrounded by a narrow zone which easily colors with orange. Moreover, the polynuclear neutrophile cells may also occur; but the most characteristic cells are the basophile young plasma cells, which, it must be remembered, are very unusual in the really normal connective tissue, and are pathognomonic of chronic morbid reaction. The kidney-shaped mononuclears and the active macrophages and the eosinophiles may also be present.

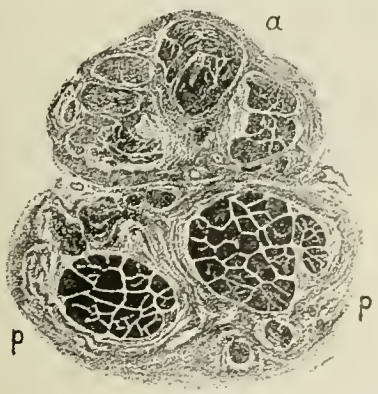

FIG. 2.—Extensive and marked perineuritis which has not yet implicated the fibers of the posterior root bundles (p p), but has seriously invaded those of the anterior root (a). Many of these latter are quite degenerated, sbown by their disorganization and failure to stain. A radicular nerve of a taboparetic, the second sacral. X 10. (From Nageotte.)

Now, although such appearance always occurs in syphilis of the nervous system, yet we cannot affirm that they are syphilitic in nature until we find the

Treponema pallidum, or find some antibody to it. The reaction devised by Wassermann is not at present believed to be really specific in the sense in which Bordet and Gengou first devised the principle. For absolute rigor we must therefore fall back upon the law of invariable succession.

Fig. 3.—Sections of spinal cord of a tabetic (Case IX), showing a degeneration of the posterior columns of Goll and Burdach along their whole extent with conservation of the cornu-commisural zone, and some other endogenous fibers only (Weigert), A, cervical region; B, lower dorsal; C, fourth lumbar segment; D, sacral region.

A most important advance in our knowledge of this succession has been made by the researches of Vincent. He has had occasion to puncture the arachnoid sac of a large number of patients with and without syphilitic history, the latter sometimes showing only a single symptom, such as paralysis of the third, sixth, seventh, or eighth nerve. He has also punctured the subarachnoid cavity just after the onset of symptoms. In all of these he has found considerable lymphocytosis, and it seems absurd to suppose that a reaction of this nature is not indicative of chronic meningitis antedating for a considerable period the nervous symptoms for which the patient consulted, which had lasted only a few days in some instances.

Another powerful argument is the fact that considerable lymphoid infiltration has been found in the connective tissue surrounding nerves whose functions were apparently unaffected during life, and similarly the pia mater also presented extensive exudates where no mental symptoms had appeared.

But for absolute proof one would require the most systematic punctures of all syphilitics long before they present the tertiary nervous symptoms; and Vincent has reported five cases of this kind. In all the first three patients, nerve symptoms have already shown themselves; in one, diffuse meningoencephalitis; in the second, a double hemiplegia; in the third, a neuritis of both eighth nerves.

Case I.—A man, 42, in April, 1898, felt tired and had occasional headache. Treated for syphilis twelve years before. There were no signs of disease of the nervous system, except that the right pupil was smaller than the left, and contracted less freely and extensively to light, both direct and consensual. It was this sign which compelled the lumbar puncture, although he had no change in speech, loss of memory, disorientation, or change of humor, and had been at work up to the day before. Enormous lymphocytosis was found. The patient was again seen six months later. He was emaciated, stuttered, could not repeat correctly the test phrases, his tongue and face trembled, he was untidy, forgetful, not being able to find his way home; in short, all psychic and somatic signs pointing to general paralysis. The right pupil reflex, however, was in the same state as at the first examination. Thus, lymphocytosis was a sign indicating chronic meningitis preceding general paralysis.

Case II.—Man, 52. Syphilis, 1892. Treated three months by injection, and two years and one-half with mercurial pills; later potassium iodide. During the secondary period he had had articular pains except when heated by movement. Later a severe permanent headache, diurnal in type (he worked at night as a baker). Slight alcoholic gastritis had troubled him, but was easily cured in 1898. The joint and head pains persisted, so the meninges were punctured, and the liquid was found to abound in both lymphocytes and polynuclears. Two further punctures revealed the same lymphocytosis, but no objective nerve symptoms were present, until one night in October, while at work, he

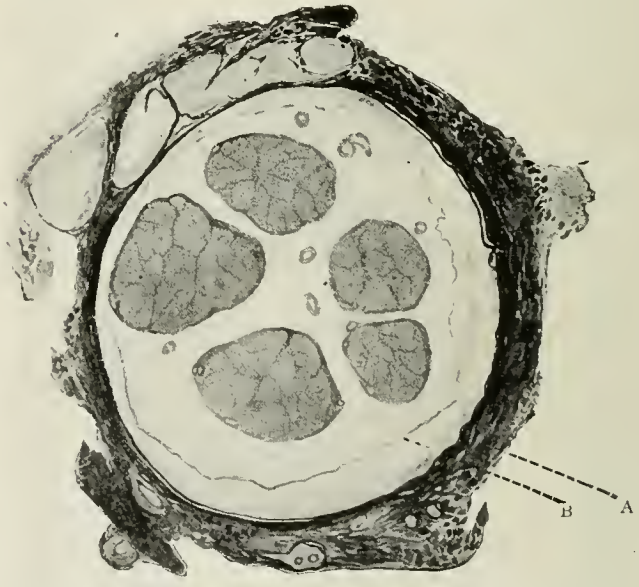

Fig. 4.—Transverse section of normal hypoglossal nerve after its fascicles have collected into the common meningeal sheath which surrounds them before they enter the anterior condyloid foramen. This situation is the homologue of the "radicular zone" of the spinal roots. Note the thin single layer of arachnoid matter and the equality of size of the nerve fibers and medullary rings which are alongside one another (Van Gieson stain). A, dural sheath; B, arachnoid sheath.

had a fit, followed by a complete paralysis of the face and all four limbs. He could not even swallow. Liquids were given through the nose. He had ptosis, saw double, and the tongue was clumsy. On

mercurial treatment, he began to walk and swallow. Three months later the left deep reflexes were greater than those on the right, which presented the platysma sign. The association movement of the thigh and pelvis was impaired on the right side.

Fig. 5.—Similar section of hypoglossal nerve of this patient, see Case IX, showing thickening of the arachnoid. Round fasciculus (1) and also on the inferior aspect of fasciculus (2), connective tissue areolæ are separating the nerve fibers into groups (Van Gieson stain).

Swallowing and speaking were still affected. There was no irideplegia, but lymphocytes were still abundant. There was apparently a partial thrombosis of the basilar or its branches, for the pyramidal and geniculate tracts were implicated, as well as the cranial nerves. Thus for at least a year chronic syphilitic meningitis, as evidenced by lymphocytosis, had been present before cerebrospinal syphilis declared itself symptomatically.

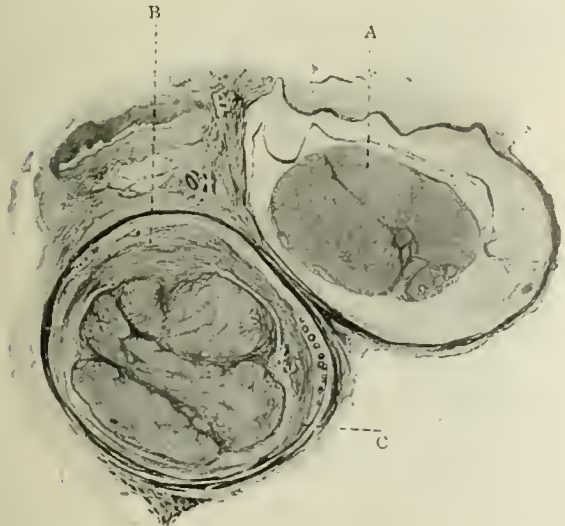

Fig. 6.—Section of same nerve nearer its exit. Fasciculus A now shows only a slight endoneuritis. Its arachnoid sheath is now almost normal in thickness; while fasciculus B shows intense endoneuritis and a greatly thickened arachnoid (Van Gieson stain).

Case III.—The third case of this series was that of a child aged 8. After a chancre of the lip in March, 1897, and without any secondary symptoms, beginning in May, she contracted in turn a gumma of the clavicle, and an interstitial keratitis. It is probable, therefore, that even then meningitis was present, for Vincent has never seen a case of interstitial keratitis unaccompanied at one time or another with lymphocytosis. But the girl recovered under mercurial treatment until in March, 1898, she suddenly became deaf. Tinnitus was also present; and, on examination, the labyrinthine origin of the trouble was evident, though there was no vertigo nor other sign of organic nervous disease. In spite of the treatment, the deafness increased, and in July was complete. Enormous lymphocytosis was present during all this period, and the Wassermann reaction was positive. Thus again a lesion of the nervous system appears as the third stage of a process of which the first was syphilis, and the second meningitis.

Case IV.—In the next two cases this third stage has not yet occurred. The first is that of a man of 35, having had syphilis in 1901. He received inunctions for the first two years, taking iodide between the series. He then ceased treatment for two years, after which he recommenced on account of three miscarriages by his wife in 1903, 1904, and 1905, the last one a living child with hereditary syphilis. It seems evident then that in spite of the treatment there has been no interruption in the disease between the initial chancre and the results following; for in 1907 a lumbar puncture showed abundant lymphocytosis. Yet all his nervous functions were unimpaired with the exception of a certain instability in face and speech which he has always had, but he continues at work, although he has had some trouble with his wife, and appears a little eccentric.

Case V.—A man, 24, had syphilis in 1904, without secondaries. He commenced using gray oil from the time he saw the chancre, treating himself, but soon ceased on account of the pain, and substituted a daily dose of 10 centigrams protiodide of

Fig. 7.—Still lower, fasciculus A is much atrophied; fasciculus B still shows endoneuritis, but little arachnoiditis now remains. These three figures clearly show in these two fascicules, an inflammatory area which arises, increases, shows a maximum and decreases; it deserves the name of transverse radicular neuritis (Van Gieson stain).

mercury. This he continued for three years. Then, believing himself cured, he married. However, 27 months after the chancre headache began and lasted almost continuously for 8 months. Though worse at

night, it was thought to be in turn influenzal, neurasthenic, and neuralgic. On examination, no signs of organic nervous disease were discovered, but punctures showed a tremendous lymphocytosis, such as appears in the most active cases of general paralysis. Indeed, the diagnosis could have been made with the naked eye, the liquid showing a peculiar opalescence characteristic of an abundance of cells. In addition to the usual cells there were some polynuclear and eosinophile, and also some plasma cells. He was at once treated by intravenous injections of mercuric cyanide every other day to the number of thirty in all. The headache quickly disappeared, but he was then given six injections of gray oil and four series of six injections of emul-

Fig. 8.—Section just above that of Fig. 5 (B is cut longitudinally as it bends), stained with hematein and eosin to show the infiltration of round cells and the progressive thickening of the arachnoid as it descends to embrace the nerves; note the granulomata. C, artery and vein; D, arachnoid, growing thicker as it ascends.

sified calomel. He might have been considered as cured but for the appearance of a pharnygeal gumma 6 months later, and but for the persistence of the intense meningitis shown by the lymphocytosis.

The future of these patients will contribute to the solution of a medical problem of great importance, for if it is ever shown that specific treatment can remove chronic meningitis, it will be necessary to puncture systematically all cases of syphilis, so that the meningeal trouble may be detected in its incipiency and before causing irreparable lesions of the nervous system.

But it had been known since the researches of Ravaut in 1903 that meningitis often occurs in the secondary period, and is sometimes even followed by lesions of the nervous system, facial palsy and neuralgia being the most common, so that it is very important to know whether the tertiary meningitis

Fig. 9.—A perivenous granuloma of Fig. 8 under a high power; note the commencing organization of the cellular elements. A, artery; B, vein.

really has been preceded by a latent secondary one. The following cases are instructive in this regard:

Case VI.—A single woman of 30 had a chancre in 1900. Facial paralysis six months later. In December, 1902, only a slight spasm remained. At that time considerable lymphocytosis was present. After four series of gray oil injections, the lymphocystosis was still present. It was not until four years had elapsed that there was any considerable amelioration. There were only five or six lymphocytes in each field, and this improvement

Fig. 10.—Fascicule A (Azoulay stain); note in *a* some fibers uncolored or small, and the progressive diminution of colored fibers, in *b*, *c*, and *d*.

still continues; so that she may be regarded as out of danger for the time being at least.

Case VII.—A single woman, 28; had roseola in 1901, and numerous secondaries. In 1903 trigeminal neuralgia, more especially frontal, which was

followed by a double hemorrhagic retinitis. An enormous lymphocytosis was present. A year later, right hemiplegia and aphasia appeared, the symptoms of which were practically well a year after She was punctured periodically until October, 1908,

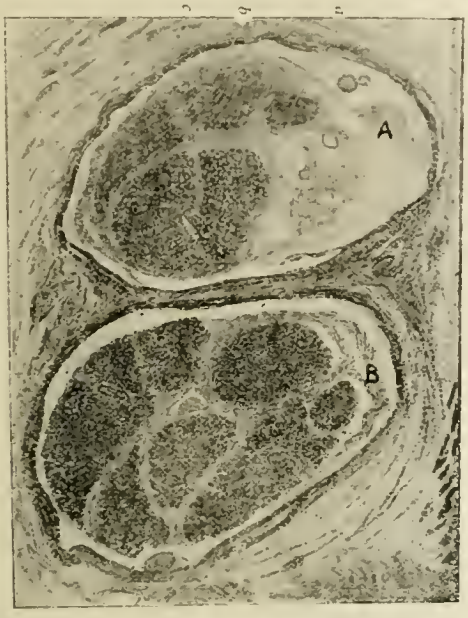

Fig. 11.—Part of the pneumogastric nerve of same Case IX, showing endoneuritis and arachnoid hyperplasia; very little myeline remains in fascicles *a*, *b* and *c* (Von Gieson).

and always showed an enormous quantity of cellular elements and albumin in the arachnoid fluid.

It seems very probable, therefore, that syphilis of the nervous system sometimes may be traced directly back to the general infection following the chancre, and that chronic meningitis is merely the persistent state of the secondary period; for it must be remembered that nervous accidents may occur in the secondary period, and that examination of these reveals always a lymphocytosis, as in the case described by Sézary (Soc. de Biologie, 1908, April). It was a man of 40, who a month after the chancre showed general psoriasis, and forty days later, hemiplegia, aphasia, and death. Two lumbar punctures at a month's interval showed abundant lymphocytosis, the first having been made before the nervous symptoms had appeared.

Case VIII.—Another case is that of Dutheil (*Thèse de Paris*, 1909). It was a man of 43, who five weeks after the chancre had severe papulotubercular syphilides, showing lymphocytosis. Mercury had to be given up on account of stomatitis. Twenty-six days after he fell into a comatose state and could hardly swallow. Eight days later right hemiplegia, with Babinski sign and aphasia, and death so rapidly that no cerebral softening was found post mortem.

In both cases the same striking sequence is present of syphilitic meningitis and organic nervous disease. The rapid succession shows the relation all the more strikingly, and thus there would not appear to be the essential difference formerly supposed between secondary and tertiary manifestations.

The sceptic, however, will still require pathological confirmation of this thesis, and, although this has been given as regards the spinal root by Nageotte's researches, confirmation with regard to the cranial nerves has not been presented. Now, however, the case which follows furnishes irrefragible proof of each of the foregoing points.

Case IX.—A man of 38 entered the Salpétrière in 1907 for weakness of the lower limbs. He had syphilis in 1891, inadequately treated. He drank a great deal. In 1904 he began to have vertiginous turns and feelings of suffocation in the night. Later began girdle pains, which he thought were colic. On examination he was failing, emaciated, and appeared 60 years of age. It was a typical case of advanced tabes, with abolition of all deep reflexes and a conservation of those of the skin. He was very ataxic. The muscles were diffusely atrophied, especially in the peroneal region, and power was diminished in the pelvic girdle; but a reaction of degeneration occurred only in the right extensor communis digitorum. Sensory symptoms consisted of lightning pains, complete loss of sense of attitude (less marked in the arms), slight hypoalgesia, while the sense of touch was not impaired. There was incontinence of urine. The right pupil was larger than the left, and neither reacted to light nor accommodation. There was intermittent diplopia, due to paresis of the right internal rectus. The fundus showed a lesion. There were attacks of suffocation beginning suddenly, with cold sweats, during which occurred asphyxia, and sometimes loss of consciousness. He had also laryngeal crises, and there was paralysis of the abductors. There were no other cranial nerve symptoms.

The intelligence seemed intact, as he read the papers each day and spoke reasonably to his wife, advised the patient in the neighboring bed, and was very grateful for the care he received. This is particularly striking in view of the fact that the autopsy showed a diffuse cortical meningeal involvment; but it was merely the first stage, for the process had not invaded the pial septa; and there was no encephalitis to constitute the picture of the general paralytic brain. The process, however, had penetrated the medulla, as will be seen.

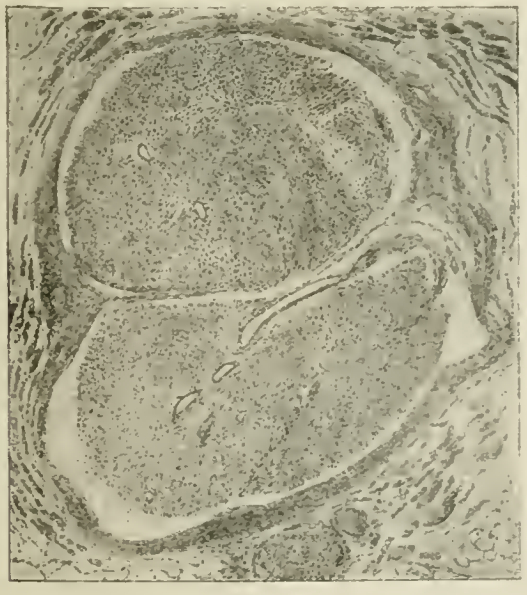

Fig. 12.—The same with hematin-eosin showing round-cell infiltration of nerve and meninges.

Autopsy.—The whole neuraxis showed an extensive meningitis. There was a very opalescent aspect of the pia mater, especially along the vessels on the convexity. At the base of the brain, on the

contrary, an enormously thickened layer of arachnoid clothed the chiasm in the interpeduncular space, and extended along the optic nerves. This was even more marked over the pons, a fibrous mat being furrowed by the facial and auditory nerves. The appearance of the cerebellum was like that of the cord. There was extensive meningitis along the posterior surface of the dorsal cord. There was a trimeningeal symphysis extending to the lumbar enlargement. No lesion of the nerve centers could be observed with the naked eye. Thus we see basillar meningitis, the first stage of general paralysis, and meningitis of developing tabes, placed before us by the same patient.

Microscopical Appearances.—The cord showed the (Fig. 3) typical appearances of tabes, with the almost complete integrity of the endogenous tracts and short exogenous fibers. The tabes is not only lumbarsacral, but also dorsal and cervical. The transverse radiculitis was present in every respect like that described by Nageotte. The cortex showed lymphocyte infiltrations of the pia matter with endoperiarteritis; but the intracerebral vessels were free, and the tangential fibers and pyramidal cells were not implicated.

The left hypoglossal and right pneumogastric were damaged at the autopsy; but, although there had been no clinical evidence of its implication, in spite of the repeated careful examination of the face and of the tongue, the right hypoglossus showed all the stages between complete health and entire destruction. The absence of clinical symptoms could be accounted for in view of the fact that only about 1-16 of the fibers were atrophied. The loss of function of the muscles supplied by these was masked by the presence of the remaining healthy fibers; for there is great interlacement of the muscle fibers of the tongue. In the oculomotor on the contrary the muscles are separated, and have to be in a state of equilibrium to their antagonists. A very small lesion will disturb the exactness of this adjustment; and a diplopia appears at a stage when mere inspection could not detect the muscular disability.

As the chain of threads of the hypoglossus emerges from its sulcus in the medulla, they normally converge and become the nerve. Its constituents become surrounded by meninges which form a funnel-shaped canal. There may be one, two, or more of these, each containing several fasciculi, which assume polygonal form from their contact with one another. Between the fasiculi is a slender network of arachnoid, containing a few vessels. The whole is surrounded at a distance by the perietal arachnoid, which again is separated from the dural sheath which surrounds this; there is very little connective tissue between, and finally the individual nerve fibers are pressed one against the other, almost free from connective tissue, which is only visible with a very high power. See figure 1 of normal hypoglossal nerve.

On comparing this with the nerve from this patient (Fig. 2), one sees an enormous increase of connective tissue within and around the fasciculi-endoneuritis. Moreover, the proliferation of the perifascicular arachnoid has joined it at one spot with the thickened arachnoid sheath, constituting perineuritis. The activity of the lesion is shown by the lymphoid character of the exudates.

In this patient there were four hypoglossal fasciculi, two of them large; and it is very interesting to study the difference of level at which these were respectively implicated in the meningeal process. The most striking fact of all, however, was that the inflammatory processes entirely ceased before the two fasciculi formed the hypoglossal trunk. That is to say, its localization constituted the complete homologue of Nageotte's radicular sac in the spinal nerves. It began even before the common arachnodural sheath, which also surrounded the filaments in a common fasciculus. It was shown by a thickening of the sheath around them, scarcely visible, and also by vascular filaments. The smaller fasciculi also showed this appearance along their nerve fibers.

A little lower down (Fig. 3*a*) the arachnoid gutter was enormously thickened, but inflammation had not yet attained its height within the fasciculi, although the nerve itself was five times its normal thickness. This progressive swelling of the perifasicular sheath is one of the most instructive facts of the whole research in that it explains why a pathological diffusive-process is, symptomatically speaking, revealed by so few definite signs. The reason why the lesion has so long escaped notice now becomes clear; for it is confined to the first few tenths of a millimeter of the sheath of the nerve. The foregoing figures show how the intensity of the lesion progressively diminishes from this point; so that four millimetres lower, the meningitis practically disappears, but its effect upon the nerve fibers is shown by their progressive disappearance, which constitutes an "atrophic" sclerosis. In fasciculus *b*, on the contrary, the atrophy was much less marked, although the meningeal lesion was as great as that of fasciculus *a*. This illustrates the rise and fall in intensity.

The facts shown by the Van Gieson stain are, however, merely quantitative. Still more striking is the picture shown when the tissue is stained by hematein-eosin-rose, which is not designed to show the collagen of adult connective tissue, but reveals the nuclei of active inflammatory cells. The nerve fiber bundles show a tremendous infiltration of small round cells and fibroblasts. The chronicity of the process is shown by the fewness of the polynuclears and erythrocytes, and this is confirmed by the thickness of the arterioles and the obstruction of the lumen by the proliferation of the endothelium. Moreover, lymphoid nodules are here and there seen, especially around the veins. These appearances show that they are still in evolution. The fibroblastic organization of intervening connective tissue is shown by the adhesion formed between the arachnoid and the several bundles, which had also extended even beyond to the duramater, which itself is inflamed.

The nerve fiber alterations are clearly shown by the methods of Weigert and d'Azoulay. The normal hypoglossus is like an anterior root in that it is composed of large nerve fibers nearly equal in circumference and almost touching one another. On impregnation with the osmotannic process, bundle *a* of the patient showed, even under the low power, to what a different degree fasciculi in the same section were implicated; thus *a* appeared nearly normal; while *b*, *c*, and *d* showed many dwarfed fibers. But the high power showed even in *a* that the fibers were abnormally separated one from the other; so that, although the fibers themselves were not yet attacked, the inflammation had

already penetrated the nerve. Some fibers, though not entirely normal, had scarcely taken the stain. This seemed to be the first indication that they were attacked. Normal and abnormal seemed mixed without plan, although sometimes the diseased occurred in bunches. Lower down, *a* showed the same appearance as in the preceding section was shown by *b*, *c*, and *d*. That the appearances are not due to the technique is shown by the normal aspect of the normal fibers in the same fasciculus. It is quite clear that the maximum damage to the nerve fibers occurs as they are traversing the inflammatory area in the meningeal sheath. It might be objected that this nerve degeneration was due to disease of the hypoglossal nucleus in the bulb; but 250 sections of the medulla failed to show any decolorized hypoglossal fibers or central softening. The meningitis was purely peribulbar, and the hypoglossal was intact within the metencephalon.

The predominant feature of the lesions of the nerve fibers is the demyelinization without loss of the cylindraxis. The loss of the myeline may extend both above and below the inflammatory focus. It may even extend to the periphery of the nerve. Unless reagents are employed which color either the axis cylinder or the degenerated myeline, one may conclude that a nerve is completely degenerated and wonder that its functions could have been maintained during life. The Weigert method shows neither the axis cylinder nor degenerated myeline; so that when conclusions are drawn from it alone, they may be fallacious. The conservation of the axones, for a time at least, explains the long continuance of the functions in nerves completely engulfed by a meningitic focus, and also why certain muscles sometimes escape, while others are implicated. Moreover, it is evident that there may occur alterations of the structure capable of modifying function and yet indistinguishable by our present technique from similar neighboring modifications of structure of sufficient intensity to interfere with function. And it is evident that if two neighboring fasciculi of the same nerve passing through the same diseased focus can be so different in their sensibility to reagents as well as clinically, still less wonderful must be the difference of the effect of the lesion in two nerves so widely separated as the anterior and posterior spinal groups.

The pneumogastric nerves were examined with the same technique as the hypoglossal; but in addition, the peripheral portions, including the two recurrent laryngeal nerves, were studied. The irregular course of the filaments forming the vagus, and their enlacement with those of the ninth and eleventh nerves made them difficult to follow. Besides, there are two ganglia on the nerve, the first, the jugular, being very far from the subarachnoid portion of the nerve. In spite of these difficulties, the preparation shows (Fig. 11 and 12) similar lesions to those of the hypoglossus. The maximum of the endoneural and perineural inflammation occurs at the point where the arachnoid is reflected upon the nerve filaments. The arteritis is also abundant, and a definite exudate in course of organization is also found at the bottom of the arachnoid funnel.

The vagus normally contains many small fibers, which make it difficult to say that any have been stricken by the disease. It is clear, however, that the pale and small fibers are more numerous in the inflammatory focus. Moreover, at this point they are scattered; whereas in the normal nerve, they are close together. It is safe to conclude, therefore, that the vagus presents typical radiculitis.

The recurrent laryngeal nerve normally contains one fasciculus almost entirely composed of thick fibers. Its other fasciculi contain about one-third of slender fibers. In this case, osmic acid shows in two small fasciculi of the nerve, only from 15 to 20 thick fibers, whereas the normal nerve contains from 50 to 60. Blocks of connective tissue, some of them containing a small spot of myeline, separate the fibers of the diseased nerve. In the thick fasciculus, which should normally consist of large fibers, slender fibers now preponderate. With the methods of Marchi, Weigert, and Azoulay only a few fibers color, and these are all large ones. It is clear, then, that there is great diminution of the fibers and that the small ones seen are abnormal. But Van Gieson's method shows a large number of intact axones and sheaths of Schwann; so that the lesion has not produced complete secondary degeneration, but only an extensive demyelinization and the loss of a certain number of large fibers. It would seem that the loss of these corresponds with the loss of the thick fibers in the fasciculus of the trunk in which the thick fibers had been destroyed to such an extent by the inflammatory lesion.

Medulla.—The nucleus ambiguus was examined from the acoustic tubercle to beyond the middle of the bulb. There was neither diminution nor atrophy of the cells on either side. The dorsal myeline was equally normal. The Weigert method showed that the axones were healthy while traversing the bulb. It is therefore clear that the laryngeal symptoms of this patient were due to a focus of transverse radicular meningitis.

LOCAL ANESTHESIA IN GENERAL SURGERY.*

BY W. S. SCHLEY, M.D.,

NEW YORK,

SURGEON TRINITY HOSPITAL, ASSISTANT SURGEON ST. LUKE'S HOSPITAL.

THE subject of anesthesia for surgical work is so much to the fore at present, when clinicians and chemists are striving not only for substitutes for our chief anesthetic agents, ether and chloroform, but for ever safer and more agreeable modes of administration, that a reminder of the accomplishments of that little cultivated branch, local anesthesia, may be of interest. The subject is not a new one and with those not constantly engaged in surgical work, as

*Read at a meeting of the Medical Society of the County of New York, Dec. 27, 1909.

well as with many who are, the possibilities and benefits of such anesthesia are often looked upon with disbelief or at least skepticism. This is largely a heritage of the old days of strong cocaine solutions and imperfect technique.

The general anesthetics in experienced hands are very safe but their employment is always marked by more or less disturbance, an evidence that anesthesia is purchased at a price which in the average case is not too high even though it be disagreeable. But in the presence of profound bacterial toxemia and especially in those suffering from grave disturbances of their own metabolism it has always been a serious consideration. Surgical endeavor has offset much of this by more rapid operative work and better technique but there will always be a certain number of cases that despite our best efforts succumb to the additional insult of a general anesthetic. These added risks in surgery are the diabetics, nephritics, those with marked disturbances of the thyroid gland, liver, and pancreas, and those with a greater or less degree of organic disease of other regions, in whom an intercurrent affection demands the intervention of surgery. For a number of these, to save added hazard, and for some condemned to bear burdens for the space of their existence because they are poor operative risks, local anesthesia is applicable and distinctly able to offer relief and to a greater extent each year as our methods are perfected and anesthetic agents of lesser toxicity or greater adaptability found.

This is no plea for the general substitution of local methods whenever possible, general narcosis has been and will remain our chief reliance probably for some years, but the place of local anesthesia in the larger surgery has come to stay and its field has steadily widened until it has successfully entered the domain of major surgery. While still at its greatest usefulness where general anesthetics add distinctly to the danger it has arrived at that stage in its development where it can in addition be extended to numbers of cases to enable them to escape the disturbances and discomforts of ether and chloroform and to ensure a quicker and pleasanter convalescence. It is now possible and permissible to operate with its aid in conditions that a short time ago were regarded as unapproachable except with complete and general narcosis.

Lack of time, lack of interest, or lack of patience has with most operators restricted its use to the usual cases of minor surgery and the technique of its employment in the larger field, not difficult but delicate, has been neglected. The tendency is to fall back upon the anesthetist and accept chances in cases not only suitable but desirable for its use. Local anesthesia must offer something more than relief from pain and discomfort and must be appreciated as a distinct advantage in many cases if not as a life-saving procedure as well. Its conspicuous advantages are the greatly reduced or total absence of shock, absence of respiratory and gastric disturbances, and the apparent absence of any other organic disturbance with a more agreeable and safer postoperative period. Even in abdominal work with the exposure and handling of viscera and in cutting operations, unless continued at length and with unnecessarily rough handling and cooling of the parts, there will be little or no evidence of shock then or later. These patients are entirely conscious and able to converse and reply to questions throughout and often to assist the operator. In exploratory laparotomy it has been my experience in several cases to have them take a deep breath at request to depress a kidney, stomach or liver to within grasp of the hand introduced through the incision. Thorough palpation of the abdominal organs in a non-inflammatory condition is apparently painless and moderately strong traction may also be exerted. Many of these patients gave no evidence of the operative work at all and not infrequently the subsequent day the operated cases could not be distinguished from those awaiting their turn. They have usually left the table with a lower pulse rate than on going on. The great reduction or absence of shock, as stated in an earlier paper, I believe due to the more or less complete nerve block, absence of abnormal heat radiation from the surface and lungs, and absence of the direct toxic action of the anesthetic upon the nerve tissue of the brain and spinal cord. The nerve block and the enforced rather gentler manipulations save the spinal cord from a bombardment of impulses while laboring under the effect of a toxic agent, and there is little or no fall in vasomotor tone. The addition of adrenalin to the anesthetizing solutions further acts to diminish the speed of absorption of the anesthetic and to maintain blood pressure.

The particular method of local anesthesia that I wish to speak of here is neither the infiltration method of Schleich, the neural methods of Crile, Matas, or Cushing, nor the venous method of Bier but one of purely local anesthesia of the tissues and cellular planes with limited amounts of the solution of the anesthetic that has accomplished, I think, as much as any one other proposed. It is especially adapted to abdominal work and in this field has undoubtedly an extended future. The undoubted painlessness in the necessary handling of gut and peritoneum in doing hernia operations and colostomy and in resecting the gut in bad cases of strangulated hernia by this method have led me to more extensive work. The excellent condition of these patients after operation was most striking, as it has been in all the cases thus far done. The knowledge and experience so gained has been used the past three years in extending the method to a number of suitable abdominal and other cases, in some of which it has been put to as severe a test as might well be expected of a more general anesthetic yet has been adequate. The anesthetic solution and the experimental work with this mixture I have reported elsewhere in detail and will only say here that it has been the novocain-adrenalin combination. The toxicity of novocain is but one-sixth that of cocaine and when combined with adrenalin it has anesthetic properties and a suitability, I believe, much above cocaine or its combinations *when injected hypodermically*. The combination with adrenalin is far less toxic than the novocain solution alone, a lethal dose of the latter for an animal having but slight action when administered together with a relatively small amount of adrenalin, with which it seems to enter into a definite combination. The novocain has been used in 2 or 4 per cent. strength with adrenalin (1-1000) solution added and in the proportion of 5 or 6 to one. The largest amount that I have used has been 140 minims of the combination of 4 per cent. novocain with adrenalin in possibly the most extensive laparotomy that has been done under local anesthesia, a case of ovarian cystoma in which the greatly adherent tumor weighed over 50 pounds. This case has also been reported elsewhere but I may be pardoned, perhaps, referring to it again as illustrative of the extent to which we can go in selected cases. It was necessary to make a 12-inch incision through the thin distended

abdominal wall to turn out the immense semisolid mass, separating and frequently ligating the adhesions to the gut and finally the broad pedicle. The operation was done in the presence of a pulmonary tubercular lesion and a general anesthetic was unwise. This patient was conscious throughout the procedure, quiet and replied to questions. She took nourishment the evening of the operation and slept some hours that night, showing no appreciable shock at any time. She had but one-fourth of a grain of morphine a half hour before operation. The thin distended abdominal wall made the section easy and all exposed parts were kept warm and covered. This patient made the statement on leaving the table that she thought that we had been trying to catheterize her, a procedure necessary on account of the bladder prolapse from pressure. The great advantages of this feebly toxic mixture in the stronger percentages, over the more dilute infiltrating solutions of cocaine or other drugs, are the remarkable diffusive action from the injection site which does its own infiltrating and the longer we wait the better the anesthesia. It will nearly always be found of wider extent at the end of the operation than at the beginning. We have the additional advantage of operating through tissues that are dry and comparatively bloodless and in which the larger vessels stand out in contrast with the paler surroundings. The action is very durable. The anesthetization of the part takes but a few moments and is less painful. Secondary hemorrhage of any degree whatsoever or interference with wound healing has never been observed; Bodine's observation that the rather gentler handling of tissues is responsible for the excellent wound healing with local anesthesia is undoubtedly correct. The past few months I have been using a new combination of novocain with synthetic adrenalin, and in one recent case of very large femoral hernia of 18 ears' duration, one and one-third grains in this mixture secured perfect and lasting anesthesia. It was possible to do all the necessary work, separating the greatly adherent omentum from the ring and the reparative suturing easily and without pain. We were handicapped in no way by the local anesthesia and the operation was as complete and as satisfactory as though general anesthesia were given. Extensive superficial dissections, with the exception of goiter, have not been undertaken, and the operations for malignant disease have always been done under general anesthesia. In abdominal work we are able to take advantage of this comparative insensibility of the viscera and peritoneum and except with a large deposit of fat in the subcutaneous tissues of the abdominal wall the procedure is not difficult and many of the less complicated as well as some of the more complicated conditions may be operated in this way. Exploratory measures for suspected tumors, obstructions, and perforations may often be well accomplished in those serious conditions in which they are so often called for and there is nothing in this method of local anesthesia to contraindicate general anesthesia at any time it may be found wise or necessary and the amount required will be much less than normally. In tubercular peritonitis, especially with lung involvement or poor general condition and in typhoid perforation it is of great value.

In amputations and in the larger operations upon the lower extremity local anesthesia and nerve blocking have to compete with spinal anesthesia, which has proven very free from reactions and systemic effects if the anesthesia does not extend above Poupart's ligament. From 15 to 18 minims of a plain 4 per cent. solution has proven very satisfactory in these cases.

But few patients object seriously to local anesthesia and not a few are glad to escape a general narcosis which they dread more than the operation. Experience proves the decreased risk even where there is a certain nervous excitement due to an appreciation of the course of the operative procedure. This is especially true in those suffering from Graves' disease and whether the operation be thyroidectomy, appendectomy, or any other procedure. The preliminary administration of ¼ grain of morphine an hour beforehand and the occasional inhalation of a few drops of alcohol and ether from a mask to distract attention are of advantage in some cases, but as a rule with increased experience less and less of these adjuvants are found necessary. Reassurance as to the painlessness of the operation and the wisdom of withholding ether are most helpful and wise, and quiet work goes far towards success. In the hysterical and uncontrollably nervous local anesthesia is impossible.

A knowledge of the variation in sensibility of the different tissues and an intimate knowledge of sensory nerve distribution is requisite for the best results. The skin is the chief seat of sensibility and the subcutaneous tissues and muscles are but moderately sensitive. The larger connective tissue bundles and the tissue accompanying the vessels have some sensation. Periosteum is sensitive but not bone, and the latter can be freely sawn and cut if its covering be anesthetized. The skull can be trephined and dura and brain exposed and explored provided the scalp and periosteum are rendered insensitive. In joints the synovial membrane is sensitive. In the abdomen the parietal peritoneum has some sensation and is best anesthetized, but the viscera and visceral peritoneum apparently have none. In several abdominal cases, where time has not been a factor, it has been possible to make extended explorations and some very interesting observations which have confirmed many of the statements of others. In two cases rather strong traction upon the mesentery of the appendix produced pain in the central and upper part of the abdomen, but ligation of the mesentery and cutting the appendix, none. In one case traction upon the gall-bladder produced pain, referred to the region of the back and upper chest. Traction upon the stomach, high epigastric and lower chest pain in front. Nausea may accompany any decided traction upon the mesenteries. In the case of a markedly retroverted and retroflexed uterus, somewhat adherent, and which was explored in an operation for another condition, pain was produced by elevating it with the hand nearly to the abdominal wall. The pain in this case seemed to be referred merely to the general pelvic region. The fundus of the bladder does not appear to be sensitive even with some cystitis and it can be freely opened. The reflexion of parietal peritoneum covering it above appears to have some sensation, as also the tissues of the prevesical space. These are easily anesthetized before beginning the abdominal incision.

In my experience at least the viscera may be very freely handled and a very fair amount of traction exerted upon their suspensions and mesenteric attachments without sensation. Cutting, burning, and stitching is entirely painless.

In addition to the abdominal and other cases reported a year ago, those of traumatic rupture of

the jejunum, two cases of intestinal obstruction from gallstone enteroliths, three of tubercular peritonitis, one of acute pancreatitis, ovarian cysts, exploratory operations, ventral and umbilical hernias, empyemas, plastic operations on the face and neck of considerable extent, excision of single and multiple glands of neck, axilla and groin, tracheotomies, and other cases. I have done further cases of tubercular peritonitis, intestinal obstruction, ventral and umbilical hernias, exploratory laparotomy, and interval operations for appendicitis, anesthetized the abdominal wall for cholecystotomy and choledochotomy, for cholecystenterostomy and a number of other cases. All of the cases of local anesthesia have recovered and done well with the exception of one tubercular case, which died of a continuation of the tubercular process before leaving the hospital. The freedom from pain and discomfort, absolute in many cases and endurable in all, has at times been most striking. With the exception of the hernia and appendix cases, all have been undertaken in the presence of acute ailments or chronic affections that would have made a general anesthetic an added risk or greatly added discomfort. Their condition and convalescence, I am sure, has been much more agreeable, if not safer, than it would have been with general narcosis. In the cases done so far the solution was injected but once and at the beginning and it has not been necessary to use an additional amount later.

There are many procedures that may be successfully carried out in appropriate cases and in those able as well as those unable to take a general anesthetic, but the character of the disease, character of the patient, and the surroundings must determine the choice of the anesthetic agent. While local anesthesia is not submitted as a substitute for general anesthesia, it has a definite and widening field of usefulness that may be increased with experience and the use of modern methods. There is a certain art in its use and operators will vary considerably in their results. While the danger from general narcosis in experienced hands and with skillful surgery is at its minimum, that from local anesthesia under similar conditions and where it can be utilized is always less.

PERSONAL OBSERVATIONS ON THE SKIN LESIONS OF PELLAGRA.*

By HOWARD FOX, M.D.,

NEW YORK.

The cutaneous manifestations of pellagra have been so accurately and fully described in the recently published monograph of Prof. Ludwig Merk (Die Hauterscheinungen der Pellagra, 1909) that it would be difficult to add anything new to what has already been said. My excuses for recording some personal observations made during a recent trip to the South are that pellagra is a comparatively new disease in the United States, and that the literature in our country is as yet rather meagre. The medical literature of Europe, and especially that of Italy, upon the subject of pellagra is indeed enormous. I know, however, of only two communications dealing solely with the cutaneous aspect of pellagra (the one by Dr. Bernard Wolff of Atlanta, Ga., the other by Dr. Isadore Dyer of New Orleans) that have as yet appeared in the United States.

At the recent national conference on pellagra I had the opportunity, through the kindness of Dr. J. W. Babcock, of studying about forty cases of pellagra at the State Hospital for the Insane. At the symposium on pellagra held a week later by the Southern Medical Association at New Orleans, a further opportunity was offered of studying a half-dozen cases. A few additional cases were also kindly shown me by Dr. Bernard Wolff at Atlanta and by Dr. Robert T. Wilson, Jr., at Charleston.

As the skin lesions of pellagra are most marked in the spring and early summer, it was inevitable that some of the cases, especially the milder ones, did not present as typical lesions as could have been desired. A few of the cases, indeed, showed no skin lesions whatever. While the number of cases was not great, it was sufficient to convince me that the cutaneous lesions observed were different from any I had ever seen in New York at the dermatological clinics or societies with which I am connected. While I have never seen any cases abroad, there is no doubt that the disease seen in the South was pellagra from the almost exact similarity of the lesions to the descriptions of certain European writers.

Dr. J. J. Watson, in a paper recently read before the New York Academy of Medicine, stated that in his opinion the "characteristics of the eruption were its symmetry and color." I agree with Dr. Watson that the symmetrical distribution of the lesions is most characteristic and striking, but do not consider that the color is as characteristic. It is true that many of the cases seen by me were in negroes, in which the question of color played no part. The eruption seen in the white persons presented a bright red color, changing to a dull red, and later to a yellowish brown. No one color, it seems to me, could be said to be absolutely characteristic of pellagra, as is the violaceous color of lichen planus, the yellow of xanthoma, or even the lean-ham color of specific lesions.

A characteristic feature of the skin lesions fully as important as the symmetry is the sharply circumscribed border seen most frequently in the patches upon the neck and hands. Indeed, the lesions upon the neck, forming the so-called "neck-band" of Casal, are absolutely distinctive, and could not well be confused with any other lesions of the skin. Several illustrations of the neck-band are to be seen in Merk's book which are almost perfect counterparts of some cases seen in the South. None of the cases presented sternal prolongation of the neck-band, the so-called "appendix fasciolæ" of Casal. Most of the cases were, however, in women, and Merk states that he has not met with this lesion in the female sex.

A striking picture was also presented by the eruption on the backs of the hands and wrists when the characteristic border was present. In many cases this border was seen not only upon the back, but also upon the front of the wrists. In the cases in which the eruption was disappearing the sharp border was no longer visible.

Comparatively few of the cases showed lesions upon the face. In one case there were lesions upon the neck and cheeks which at first glance looked much like a burn that might have been produced by carbolic acid. Some of the cases presented lesions upon the dorsal surfaces of the feet. In others the lesions involved the greater part of the legs and resembled an eczema. Few of the lesions noted upon the feet presented a sharply marked border.

Advanced case of pellagra, showing extensive eruption. Patient died four months after onset of disease. (Case of Dr. C. C. Bass, New Orleans).

While the backs of the hands, the wrists, neck and dorsal surfaces of the feet are the usual sites for the eruption, it may also be seen at times upon other locations. In the case of Dr. Watson, above quoted, typical sharply bordered patches were seen upon both elbows and knees. They might have been mistaken for psoriasis if the characteristic scaling of that disease had been present. At the symposium in New Orleans, Dr. C. C. Bass of that city demonstrated lantern slides showing the eruption upon the breast in one case and upon the foreskin in another case, in addition to lesions upon the typical locations.

Few of the eruptions which I saw were complicated by pustulation, constituting the so-called "wet cases." Fissuring, especially over the knuckles, was quite frequently noted. Telangiectases described by Lombroso were not marked in any of the cases. My attention was called by Dr. Babcock to patches of ecchymosis occurring upon both the upper and lower eyelids in crescentic patches. Had they not been entirely symmetrical they might readily have been mistaken for traumata. In full-blooded negroes the change in the color of the skin consisted simply in a jet black pigmentation, looking, as Dr. Watson described it, as if the hands had been smeared with soot. It was, unfortunately, not possible to watch the evolution of the eruption in any case through the stages of erythema, desquamation, and pigmentation, and the later resulting atrophy. An idea of the evolution of the eruption could be obtained only by observing the different stages in different patients.

In the differential diagnosis of the skin lesions of pellagra it is necessary, according to Merk, to consider only four affections, namely, sunburn, vitiligo, eczema, and erythema multiforme. The eruption of pellagra is at first frequently mistaken for solar erythema. An ordinary sunburn, however, is never followed by the marked and persistent scaling of the pellagrous eruption. The entire absence of scaling in vitiligo would at once differentiate this condition from pellagra. There are certain forms of eczema which at first might be taken for pellagra. In a case of squamous eczema the backs of the hands, in which the lesions were sharply circumscribed and symmetrical, the similarity to pellagra might at first seem quite marked. The characteristic itching of eczema as contrasted with the almost entire absence of subjective symptoms in pellagra would generally render the diagnosis clear. Bernard Wolff, in recording some observations on the skin lesions of pellagra from a study of seventeen cases (*American Journal of Dermatology*, 1909, p. 343), writes: "In the severe forms of dermatitis (pellagrous) the resemblance to an acute erythematous eczema was fairly close." The possibility of confusing erythema exudativum multiforme is discussed at some length by Merk. It does not

Case of pellagra, showing eruption upon front of right wrist and back of right hand. Pellagrous dermatitis. (Case of Dr. C. C. Bass, New Orleans).

seem as if there should be great difficulty in differentiating these conditions, as there is no scaling, as a rule, in erythema multiforme.

In no case did I happen to see the interesting condition described by Isadore Dyer in a recent communication (*New York Medical Journal*, 1909, p. 997). In case No. 3 of his series the eruption upon the dorsal surfaces of the hands was "particularly associated with the orifices of the hair follicles," and closely resembled a pityriasis rubra pilaris. In one case at Columbia, in a full-blooded negress, an eruption was seen upon the face which I would certainly have called lupus erythematosus if the patient had

not given a history of rapid appearance and disappearance of the lesions, together with other typical pellagrous symptoms.

The name erythema, by which the eruption of pellagra is generally denoted, does not appear to me to be entirely appropriate. It would seem quite proper to use the term erythema for the first stage of the disease, which resembles an ordinary sunburn and which lasts only a few days. But it seems somewhat anomalous to speak of the entire eruption as an erythema when the erythematous stage is so comparatively insignificant, while the stage of disquamation is so characteristic and of such long duration. An eruption which is called an erythema conveys the idea of affections such as erythema multiforme or the so-called toxic erythemata, which are not as a rule accompanied by disquamation. The general term of dermatitis would be a more appropriate name, in my opinion, than erythema for the pellagrous eruption.

It has long been a more or less generally accepted idea that the eruption of pellagra was caused by the action of the sun's rays upon the exposed portions of the skin. This theory, maintained by older writers such as Strambio and Frappoli, is still held by many at present, notably such authorities as Babes and Sion. That the action of the sun's rays is not the sole cause at least of the eruption would appear from the arguments of Raymond, quoted by Merk, who says that the eruption may occur on parts of the body protected by the clothing, or even in persons who remain indoors and are not at all exposed to the sun. It may reappear upon the same regions in persons who have taken precautions to protect the skin from the sun. The eruption may not be equal in extent to the area of the skin exposed. Finally, it may occur (quoting Neusser) in naked children upon the characteristic locations, although their entire bodies were exposed to the action of the sun's rays.

Reasoning from the observed fact that the eruption can appear on covered parts of the body, Nicolas and Jambon (*Lyon Médical*, 1908, p. 724) conclude that if the sun's rays are one cause of the eruption, they at least play a rôle of little importance. A very interesting lantern slide was shown by Dr. Bass at New Orleans, which would appear to prove that in this case the eruption resulted from exposure to the sun. The photograph showed the eruption upon the backs of the hands of an undoubted pellagrin. The patient had worn two rings, one of which had at times been removed, while the other had remained upon the hand up to the time of taking the photograph. Where the first ring had been worn was seen a circular band a little lighter in color than the surrounding darkened skin, while on the finger where the second ring had been worn was seen a band of normal white skin, contrasting very strongly with the surrounding skin.

The cutaneous manifestations of pellagra represent in themselves a rather harmless and unimportant symptom of the disease. They are, however, of great importance from the diagnostic standpoint. To make a diagnosis of pellagra without skin lesions the so-called "pellagra sine pellagra" would seem difficult or impossible. Merk has well said that in pellagra the cutaneous lesions are of the same importance as are the eruptions of variola, measles, and other exanthemata in the diagnosis of these diseases.

616 Madison Avenue.

RECTAL EXAMINATION AS A ROUTINE MEASURE.

By FRANK C. YEOMANS, M. D.,

NEW YORK.

ASSISTANT RECTAL SURGEON, NEW YORK POLYCLINIC.

It is safe to state that there is not a physician of any considerable general experience who cannot recall one or more instances of gross error in diagnosis through failure to examine the rectum. The American Proctologic Society has elevated the study of diseases of the colon and rectum to the dignity of a specialty, yet to-day the subject receives but scant attention by the professor of surgery in the undergraduate schools of America, the post-graduate schools alone endeavoring to supply the deficiency, signally failing, however, because of the few who take the courses in comparison with the total number of physicians. Abroad the situation is the same with few exceptions. In London St. Mark's and Gordon Hospitals are devoted to rectal diseases exclusively. On the continent the subject is covered by the general surgeon, and with what result? Evidently this, that to the general practitioner the rectum remains as of old a terra incognita.

The truth of this statement is a sad commentary on the instruction in our medical colleges. Most physicians rightly devote their lives, not to original research or even to a specialty, but to general practice. To this end it is essential that they be prepared at graduation to employ all the ordinary methods of investigation, generally recognized as reliable, in the examination of each organ of the body.

This indifference to proctology in practice has also been revealed and forcibly impressed upon my mind for years in the Department of Rectal Diseases at the New York Polyclinic. The majority of patients applying there have been treated or operated upon one or more times in other institutions without relief, often due to the fact that the attending surgeon regarded the cases as "minor" and turned them over, perhaps without examination, to the house staff for operation. The house surgeon conscientiously did his best, but failed through inexperience. What occurs in New York is doubtless also the case in other great hospital centers.

It is no exaggeration to say that this neglect, and consequent prolonged suffering and loss of time to patients, will continue so long as the capable and responsible visiting hospital surgeons hold diseases of the rectum in contempt and delegate to others the work that they should at least supervise themselves, and so long as medical schools fail to provide adequate instruction in proctology to undergraduates.

In pursuing the refinements of some of the newer methods of diagnosis, because of their novelty and theoretical appeal, we are prone to overlook the old but simpler means of examination and forget that they too have been improved upon.

The anatomy and physiology of the colon and rectum have been carefully studied and are fairly well understood, but the pathology has been comparatively neglected till recent years. In general it may be said that the lesions here are the same as those of other parts of the alimentary canal plus these special conditions arising from the irritation of feces, infections, and trauma to which the rectum is peculiarly exposed.

There is no class of ailments more painful, distressing, and dangerous than those of the rectum, and withal none that yields more readily to proper treatment. If we will but consider the rectum as

a comparatively isolated organ anatomically, in that its blood supply comes mainly from a single and accessible source, viz., the superior hemorrhoidal; that its lymphatics converge to the presacral glands and cellular tissue, except of the terminal one and one-half inches which empty into the inguinal glands; that physiologically it is not essential to the human economy and that the entire organ is easily accessible to examination, the subject of proctology is much simplified. By proper examination we can to-day determine absolutely by touch and sight the lesions of the lower ten inches of bowel, and the adjacent parts.

False modesty and fear of the procedure on the part of the patient may prevent him seeking relief for rectal symptoms till forced to it by pain, discharge, or irregularity of the bowels, while prudery or inexperience may deter the physician from insisting upon an examination. As a consequence, the patient almost invariably makes his own diagnosis of "piles" or "fistula" and the physician prescribes only, with the result that rectal diseases are commonly neglected in their early stages. The physician who thus prescribes is no less culpable than one who treats a pain in the chest without examining the thorax.

A rectal examination presupposes a thorough family and personal history; a general physical examination, particularly of the abdomen, and symptoms referable to the lower bowel. It is essential that the general practitioner be familiar with the latter for he usually sees these patients before the specialist.

These symptoms may be summarized briefly as follows: Gastrointestinal.—indigestion, obstinate vomiting, flatulence, irregular action of the bowels, a feeling of "unfinished business" after stool, due to prolapse of the sigmoid, constipation or diarrhœa continuing after the bowel is rid of all irritating material and not controlled by the usual medical measures, or "urgent morning stool" with the passage mainly of gas and mucus more or less tinged with blood. The latter type of bowel action is one of the earliest symptoms of neoplasm or extensive ulceration of the lower intestine.

Pain referred to the rectum, or a feeling of dragging, weight, and pressure within the pelvis or over the sacrum; reflex pain, especially down the left leg, simulating sciatica; dysmenorrhea in young women, dysuria without discoverable lesions of the urogenital organs, swelling of the left leg, chlorosis, anemia, and loss of weight. In young children, picking the nose, disturbed sleep, scratching the anus, and straining and protrusion at stool. Mucus, pus, or blood in the feces. Thus rectal diseases have many symptoms common to affections of other organs related anatomically or reflexly. This is notably true of the urogenital organs in males, reproductive organs in females, and of the nervous system. For example, prolapsus recti may follow the straining incident to hypertrophied prostate, hemorrhoids may depend upon uterine fibroids, and a feeling of fulness in the rectum with hemorrhoids and persisting after removal of the latter may be one of the earliest manifestation of tabes dorsalis. Hence it is essential that the proficient proctologist be skilled in gynecological, genitourinary, and neurological examinations, lest he fall into the error of treating the manifest rectal disease unsuccessfully because he has not recognized its primary cause. This does not mean that the proctologist is to be a general specialist, but that he must have a diagnostic horizon sufficiently broad to weigh one feature of the case against another and not be misled by the obvious lesion.

As to the investigation proper I proceed as follows: The patient loosens all constricting clothing and with bowel empty assumes the left lateral (Sims') posture, exposed to a good light. Anticipating pain, the patient will be gratified to have the examination carried out without experiencing more than slight discomfort. The buttocks are separated and the perianal region inspected. Absence of fat in the ischiorectal fossæ is suggestive of a wasting disease, *e. g.* tuberculous or malignant. We also note the soggy and moist, or dry and brittle skin of pruritus ani, abrasions as from scratching, pediculi, or worms, excrescences as condylomata, the openings of fistulæ and a relaxed or contracted anal canal. The examiner next makes pressure with the index finger just outside the sphincter in succession all the way around the anus. Thus he will often feel and be able to follow up an old tract of induration and elicit pain of a deep inflammation that would otherwise be overlooked. The patient is now instructed to "bear down" while the examiner gently teases out the mucosa, thus everting the entire anal canal and exposing any fissures or hypertrophied papillæ. Hemorrhoids are protruded at the same time and their sight and character noted. If a painful ulcer is present it may have to be cocainized before proceeding, but under no circumstances let the examination rest at this point, for we must ever bear in mind that every peri-anal evidence of disease may be but the outward expression of a more serious and primary lesion within the bowel. Thus pruritus may be secondary to catarrhal proctitis, abscess follow fistula, fissure depend upon constipation and give reflex symptoms of urethral stricture or vesicle calculus, while hemorrhoids may be due to a variety of more important causes, ranging from cirrhosis of the liver to stricture and neoplasm of the rectum. It has been my experience to see a number of patients previously operated upon for "bleeding piles" although a cancer then existed within reach of the examining finger, and for whom the earliest and most favorable time for operation was lost through neglect of this simple but all-important procedure.

The index finger, its nail-groove filled with soap, and well lubricated with vaseline or stiff jelly, is next introduced into the rectum. As it passes the sphincter the normal, the spasmodic or the atonic state of that muscle is noted and each of its segments in turn is pinched between the examining finger and thumb. A tender spot or minute area of induration may thus be felt that would otherwise escape notice. Between the sphincters the palmar surface of the finger detects any slight depression or elevation, painful or not, which suggests the internal opening of a fistula and, in rare instances, an exquisitely tender spot—an inflamed crypt of Morgagni.

Within the bowel the finger can reach a distance of about four and one-half inches. An ampulla crowded with hard feces suggests constipation or worse, impaction. Foreign bodies commonly lodge within reach. When the bowel is empty, voluminous folds of mucosa enveloping the finger high in the rectum indicates sigmoidal prolapse. If polypus is suspected the finger is first passed high and then drawn down, otherwise the polyp is apt to be pushed up out of reach. Most fibrous strictures can be felt, for roughly over 75 per cent of them occur within this palpable zone, owing to the factors there

present favorable to their development. Of 55 cases reported by A. B. Graham* 54 were within three inches of the anus.

Neoplasms—benign rectal growths, adenomata—are by far the most frequent, their commonest site being the posterior wall within reach of the finger. Fibromata occur in adults and are usually easily felt. Myxomata are seldom encountered. Among malignant growths sarcomata are rare, infiltrate the bowel wall, the mucosa not ulcerating early, and impart to the finger a leathery feel. Carcinoma is preeminently the growth for our consideration; 84 out of Tuttle's† 100 operated cases being adenocarcinoma. To touch it varies according to the stage of development—tumor, ulceration, characteristically friable, or infiltration of adjacent organs. In the digestive canal the sigmoid and rectum are the commonest sites of cancer, about 80 per cent. of the cases occurring here, next the stomach, and then the hepatic flexure. When we recall that the major number (54 of 87 of Tuttle's cases) are within reach of the examining finger and further that most of them are the final expression in the change from benignancy to malignancy, the subject assumes vital importance. According to Mayo over one-half the cases of carcinoma of the stomach give a history of ulcer, and in the light of recent pathology we must regard chronic irritations, ulcers and benign growths of every sort as potential cancers.

Outside the bowel the induration of deep abscesses and hard fistulous tracts can be felt as well as enlargement of the presacral lymphatics, a matter of great prognostic import, and the normal or painful condition of the nerves at the tip of the coccyx (coccygodynia). At the same time the state of the prostate in men and of the uterus and annexa in women is noted. Since the finger per rectum can feel about one inch higher in the pelvis than per vaginam, the former has a distinct advantage in palpating the contents of Douglas' cul de sac and the reproductive organs, excepting only the cervix and vagina. By combining suprapubic pressure with the free hand an intestinal growth may at times be brought within reach, vesicle stone occasionally felt, and cancer of the bladder and prostate palpated. General anesthesia, however, is usually required to make bimanual examination advantageous. As the finger is withdrawn, discharge, if present, follows, that of carcinoma being characteristic and diagnostic. Should the examination have indicated disease of the anal canal or lower two inches of rectum, the lesion can be viewed directly by inserting a small-sized Sims' speculum, using the finger as an obturator, on the side opposite the affection.

The squatting posture is of distinct service in causing a prolapse of the first or second degree to protrude and will sometimes bring a growth that cannot otherwise be felt within range of the examining finger.

Let it here be noted that all this information has been obtained without instruments but solely by the eye and finger. In fact, the segment of the rectum responsible for the majority of the diseases of that organ can be so examined. It is sufficient for the general practitioner that he be able thus to recognize the greater number of rectal ailments.

Having examined as detailed a patient giving unmistakable symptoms of rectal disease without finding the cause thereof, our resources are by no means exhausted, but recourse must be had to instruments of precision. The familiar Kelly tube has been elaborated by the addition of an electric bulb and inflation apparatus into a proctoscope of which there are many examples. By these instruments the terminal 8 to 12 inches of colon, the former stumbling block of the diagnostician, has been brought from darkness to light. What was surmised and treated empyrically is now clearly seen and treated scientifically. The pale, succulent, mucous-flecked membrane of hypertrophic proctitis contrasts as strikingly with the dry, red mucosa of the atrophic type as does the analagous condition of the nose. Ulcers are seen, their character and number noted, and smears taken directly from their surface for microscopic examination.

Prolapse of the sigmoid, a common cause of constipation and dragging pains, is observed, as well as adhesive bands which prevent the bowel from rising out of the pelvis when inflation is attempted. Polypi may also be seen, the long pedicles of which allow them to slip beyond reach. Strictures and neoplasms can be inspected, tissue removed by forceps for microscopic examination and, provided they do not encroach upon the lumen to the degree of obstruction, the proctoscope passed beyond determines the extent of the growth and the condition of the mucosa above, invaluable data from the operative viewpoint.

Only recently a patient was referred to me in whom I succeeded in passing a tube of small caliber and so could demonstrate in advance of operation that the mucosa above the stricture was healthy and that the bowel with the stricture could be amputated by the perineal route alone, which was successfully accomplished.

The technique of proctoscopy is simple but precise. Numerous observations are required before one can recognize the normal bowel, and broad experience is necessary to interpret its many affections. In practice anesthesia is a disadvantage, except in cases having exquisitely painful lesions. The requirements are that the patient have his clothing loose, bowel empty and assume the *correct* knee-chest posture. The finger always precedes the tube which is introduced as far as possible before the obturator is withdrawn. The instrument is then advanced, under direct vision, in the lumen of the inflated bowel with perfect safety, and is of the utmost value for diagnosis and treatment.

With the advent of the proctoscope hard bougies, formerly relied upon for the diagnosis of stricture and unfortunately still used by some, should join that other instrument of torture, the bivalve rectal speculum, as memorials of a dark and painful past.

Introduction of the whole hand into the bowel, as advocated by Prof. Simon, is valuable in cases with an angle at the rectosigmoidal juncture too acute to allow the proctoscope to pass, but should never be attempted by a hand measuring over 25 cm. in circumference.

As a last resort laparotomy is occasionally necessary, with every preparation at hand to do any surgical work found necessary. Yet Ewald has truly said, "Exploratory incision is all well enough, but we cannot expect the whole community of possible suspects to submit to being opened for inspection in order that the occasional case may receive early operation." It is therefore incumbent upon medical schools to provide adequate all-around instruction, and it behooves us as physicians to urge this course upon them, meanwhile perfecting ourselves in and employing every means of diagnosis, especially

*Transactions Am. Protologic Society, 1909.

†*New York Medical Journal*, September 5, 1908.

those simple measures detailed, which yield much and valuable information without pain or risk to the patient.

[Naturally, I omit, as being beyond the limits of this paper, the consideration of the functional capacity of the intestine as determined by the test-diet and examination of the feces.]

Conclusions: 1. Rectal examination should be a routine measure in examining patients with symptoms referable to the lower bowel. 2. Its omission frequently leads to error in diagnosis, especially in obscure ailments. 3. Medical schools should provide instruction in proctology and the profession should urge this course upon them.

SERODIAGNOSIS OF SYPHILIS.

WASSERMANN TEST.

By JUSTIN DeLISLE, M.D.,

NEW YORK.

Beginning with a study of the mechanism of hemolysis, there have been gradually added to that phenomenon many interesting and important results from scores of observers. Owing to the basic principles involved in the hemolytic reaction, a brief review will be permissible. The hemolytic reaction, or hemolysis, means that when the blood of a certain animal is injected into the body of another animal of another species there is generated in its organism, and found in its serum, a body that has the power to dissolve the blood corpuscles of the animal that furnished the blood for the injection. This reaction is not confined to the cells of the blood alone, for further exploration of this field of research has extended the elements of this reaction almost to the limits of animal and vegetable cells. Continuing this same reaction into the realm of bacteriology, we find a strikingly illustrative example in the granular degeneration and ultimate destruction of the vibrion of Asiatic cholera, when a culture of this microbe is injected into the peritoneal cavity of an animal that has been vaccinated with cultures of the vibrion of Asiatic cholera. This reaction (Pfeiffer's) is bacteriolysis instead of hemolysis; for the latter, blood corpuscles are used as an antigen, whereas microbes furnish the antigen in the former.

A more intimate study of this process has revealed the presence of two different bodies contained in the serum of an animal vaccinated with an antigen and it is upon the conjunction of these substances that hemolysis or bacteriolysis depends. The first body is called the complement, and is found in the blood serum of all animals. This substance is destroyed by a temperature of 58° C., prolonged for one hour, and is therefore thermolabile, or by allowing serum containing the complement to remain at room temperature for several days (tempolabile). The other body found only in the bloom serum of an animal vaccinated with an antigen is called the amboceptor, and, unlike the complement, is neither thermolabile at 58° C. nor is it tempolabile.

We come now to the very essence of the reaction, namely, the *specific affinity* of the amboceptor for the antigen. As noted above, antigen is any body which, when injected into an animal organism, will excite the production of an antibody (amboceptor). An antigen may be blood globules or microbes, and the specific amboceptor found in the serum of animals injected with these several cells has an affinity only for the particular cell injected.

Without even enumerating the many valuable and varied applications of the phenomena of hemolysis and bacteriolysis, let us call attention to one, the Wassermann reaction. Keeping in mind the fact that the amboceptor has a specific affinity for the particular antigen—be it blood corpuscles or microbes—at the same time let it be understood that an amboceptor is always present in the blood of an animal while suffering from a particular disease or having been injected with a known antigen. In either case the amboceptor found in the blood of the diseased animal should have a specific affinity for the particular microbe causing the disease. For example, during the progress of a case of typhoid fever, an amboceptor is generated and found in the blood serum of the individual, and when this serum is mixed with a culture of typhoid bacilli, and to this mixture fresh serum from any source (containing the complement) is added, we witness the phenomenon of bacteriolysis, but should we substitute for the culture of typhoid bacilli the culture of some other microbe, no action would take place. Therefore, we return to the point so much insisted upon, viz., the specific affinity of the amboceptor for the antigen. Neither the complement nor the amboceptor *alone* has the power to produce bacteriolysis or hemolysis; it requires the conjunction of both bodies, and the mechanism of this reaction proceeds in the following order: The first step is the union of the particular amboceptor with the particular antigen, whereupon this combination permits the complement to complete the solution. The application of this reaction in the Wassermann test for syphilis is based upon the above-described phenomena.

Careful examination of the different secretions and excretions of the syphilitic, and a particular investigation of the organs of the syphilitic cadaver, especially the organs of the macerated syphilitic fetus, resulted in finding in the liver of such a body an enormous number of *Treponema pallidum*, the supposed exciting cause of syphilis. Therefore, given a case of syphilis, even of brief duration, it is reasonable to presume that a certain amount of the special syphilitic amboceptor has been formed, and all that now remains to prove the presence of syphilis is to bring the *Treponema pallidum*, if this is the real cause of the disease, in contact with the specific syphilitic amboceptor and the complement, which can be obtained from any fresh blood serum; or if the syphilitic's own blood is examined when freshly drawn, lysis of the *Treponema pallidum* should be immediately observed. Unfortunately, up to this time no method of culture has been devised for the *Treponema pallidum;* for this, however, Wassermann has substituted an extract made from the syphilitic liver, because, as stated above, the syphilitic liver, especially the liver of the syphilitic fetus, contains a large number of the organism mentioned. Now, in order that the Wassermann test may be plain to the eye, still another manipulation has been added, and is called the diversion of the complement.

Therefore, the Wassermann test, in its entirety, means that the serum of a syphilitic, containing the specific syphilitic amboceptor, is mixed with the syphilitic liver extract, which includes the *Treponema pallidum*, whereupon these two bodies unite and are ready for the complement, which is supplied by adding fresh serum from any source. As a result, we witness the phenomenon of lysis, for we have the conjunction of the two necessary bodies,

viz., the specific syphilitic amboceptor and the complement, as well as the particular microorganism for which the amboceptor has a special affinity. If either of these bodies in this case should remain free, it means that the specific germ of syphilis is not present, and lysis has not taken place. In order to demonstrate this, some other cells, such as red-blood corpuscles, that have been sensitized by union with their own specific amboceptor, are added, and the complement which was not fixed by the *Treponema pallidum* will immediately unite with them and cause hemolysis.

The Wassermann reaction as a test for syphilis has been practised for some time in numerous laboratories, and some very curious results have been observed. This test in a high percentage of cases of syphilis gives a positive reaction, but when we come to add the negative results in undoubted cases of syphilis to the positive reaction we get in diseases other than syphilis, we begin to question not the reaction, but rather its interpretation. Further inquiry by a number of observers has justified this question when by substituting for the syphilitic antigen such substances as an extract of non-syphilitic liver extract made from normal guinea-pig heart, lecithin, sodium oleate, glycocholate, and taurocholate, cholesterin, glycogen, etc. How can these facts be reconciled with the positive statement that the specific amboceptor has specific affinity for its antigen? As in syphilis we undoubtedly have a specific amboceptor in the blood serum of the syphilitic, and this particular amboceptor should have a specific affinity for no other cell than the *Treponema pallidum* contained in the extract of luetic liver, this would be in perfect harmony with the mechanism of bacteriolysis; but when we find that an extract of nonsyphilitic liver acts just as well, it certainly puts an interrogation point after the *Treponema pallidum* as the microorganism of syphilis.

313 West Fifty-seventh Street.

REPORT OF A CASE OF THROMBOSIS OF THE LEFT ILIAC VEIN.

PROBABLY DUE TO PRESSURE OF DISTENDED BLADDER.

By C. S. AITKEN, M.D.,

ASSISTANT PHYSICIAN,

AND

J. ALLEN JACKSON, M. D.,

Those who have dealt with the insane appreciate fully the elusiveness of some patients, and the extreme difficulties which arise in trying to offer them the most careful treatment. The following case also illustrates the fact that in these cases, even though they are up and around the wards, they do not call the attention of the physician or attendant to their various ailments.

History.—M. F. was admitted to this institution October 25, 1895. Her physical condition at that time was apparently good. Mental condition: she was restless, sleepless, and melancholic. She talked constantly of religion. She was intemperate and used opium. She was married but had no children. Since admission she has shown considerable dementia, was never violent, untidy, or incontinent. She had some impediment in speech. Her physical condition was good. She was permitted to work in the dining-room.

Physical examination made by Dr. C. T. King September 24, 1908, revealed the following: Fairly well nourished and developed woman about 44 years of age. Height 155 cm. Weight 140 pounds. Complexion dark, expression of face, eyes, and mouth worried. Skin pale, rather loose, and dry. No eruption. Hair dark brown. Speech slurring—but she answers questions and speaks coherently. Eyes blue, pupils react to light and accommodation. Right pupil irregular. Voice nasal, slightly stammering and indistinct. Lids, conjunctiva, and cornea clear. Auditory apparatus normal. Nose normal. Mouth small and closed. Teeth poor. Gums normalino odor. Palate, tonsils, and pharynx negative. Tongue medium-sized, rough-coated, but no deviation or tremor. Thorax large and well nourished, good expansion. Spinal column negative. Lungs resonant throughout. Heart sounds are rather distant and of poor quality. No distinct murmurs. Pulse 80 normal volume, regular rhythm, equal, and synchronous at radials. Abdomen and viscera negative. Reflexes superficial and deep normal. No general symptoms, such as headache, vertigo, or fever. No signs of paralysis, evidences of injury, deformities, marks, scars, ruptures, etc., present. Gait, station, general coordination good. No muscular twitchings. Muscular strength good. Tactile, thermal, and muscular sense normal.

Present Illness.—Three weeks prior to death serious symptoms arose. She showed swelling of both lower extremities—the left more marked than the right. Examination proved marked swelling and pitting of both extremities, without paralysis, signs of inflammation, or evidences of gangrene. Lower abdomen showed a globular mass extending to the umbilicus. By catheter 30 ounces of urine were removed and submitted for examination. It was reported to the ward physician by the attendant that the patient had been voiding urine regularly—which, however, in the light of subsequent events—must have been the overflow of retention. Catheterization was necessary every seventh hour. There was little fever at any time. Heart gave evidence of a mild myocarditis, but no endocardial lesion was present. Following catheterization upon two different occasions vaginal examinations were made, but failed to reveal any abnormalities.

The swelling in the right leg subsided four or five days before death, while in the left leg the swelling only partially subsided prior to death, which ensued from gradual exhaustion August 17, '09.

Blood examination made August 12, '09, showed hemoglobin, 68 per cent.; red cells, 4,130,000; white cells, 13,500. Polynuclears, 68 per cent.; small lymphocytes, 18 per cent.; large lympocytes, 14 per cent.

Urine Report.—Specimen submitted August 9, 1909, was pale yellow acid, s.p. gr. 1.012. Negative for albumin, sugar, indican, and bile pigment. Microscopically showed few leucocytes, amorphous and triple phosphates. Specimen submitted August 13, 1909, was yellow and turbid. Alkaline, sp. gr. 1.010. Whitish sediment. Gives a positive reaction for albumin. Negative for sugar, indican, bile pigment. Microscopically it showed numerous pus cells. Amorphous and triple phosphates. Negative for casts.

Pathological Report.—Body that of a fairly well preserved middle-aged woman. Abdomen is prominent, marks are present, which evidently indicate former pregnancy. A small papilloma is situated three fingers breadth above the umbilicus in the

median line. There is slight brownish discoloration over the ensiform cartilage. The left leg is larger than the right. It pits upon pressure around the ankles and for about two inches above the ankle. At the inner portion of the thigh near the gluteal region there is an abrasion involving the deeper layers of the skin. Also a slight abrasion over buttocks. Labia are large and there is a slight leucorrheal discharge. Eyes bluish gray, pupils equal measuring 5 mm. Teeth not well preserved. Locomotory system negative. Circulatory system: Pericardium negative. No fluid in cavity. Heart, aortic, tricuspid, mitral, and pulmonary valves slightly sclerotic. No evidences of vegetations or any recent acute condition. Heart otherwise negative. The left iliac vein is much larger than the right. Upon dissecting out the iliac vein (left) the vessel is found to be firm and irregularly distorted. On opening the vein, older and recent clots are seen. The most organized portion being about two inches below the beginning of the iliac. Here the clot is pale in color and has attempted organization. The left external iliac as well as the femoral down to the popliteal space shows clots of blood. The right iliac is collapsed, showing here and there a small amount of sero sanguinous fluid. Respiratory system. There are no pleural adhesions, save for a few fibrous bands upon the right side posteriorly. The lungs show bronchopneumonia. Alimentary system. There are a few chronic peritoneal adhesions in the inguinal region. Intestines and stomach negative for gross lesions. Pancreas and gall-bladder negative. Liver shows congestion. In the right upper hypochondrium at the hepatic flexure of the colon and within the layers of the mesocolon is a clot of blood about the size of an egg. The attachments of the superior and inferior mesenteries also show distended vessels, and in this region there is distinct discoloration. There are no gross lesions of the adjacent viscera. Genitourinary apparatus. There is a suppurative cystitis, and acute ureteritis upon the left side as well as acute inflammatory condition of the pelvis of the left kidney. The uterus is retrodisplaced. The tubes and ovaries negative. Slight leucorrheal discharge. Glandular system. The spleen, bronchial, and mesenteric glands, adrenals, and thyroid negative.

In the absence of other conditions which would give rise to emboli or cause thrombosis, we are led to believe that this is a case of thrombosis of the iliac vein probably due to pressure of a distended bladder of indefinite duration. It is submitted for publication to impress upon the ward physicians that cases showing swelling of the lower extremities are not always due to diseases of long standing, but may be due to acute readily remedied causes and the examination by all means should include examination of the bladder. The peritoneal hemorrhage was probably due to a small embolus coming from the iliac vein plugging one of the branches of the mesenteric vessels. This accompanied by rise of arterial pressure resulted in rupture of the vessel involved. We are indebted to Dr. E. D. Martin for assistance in the pathological examination.

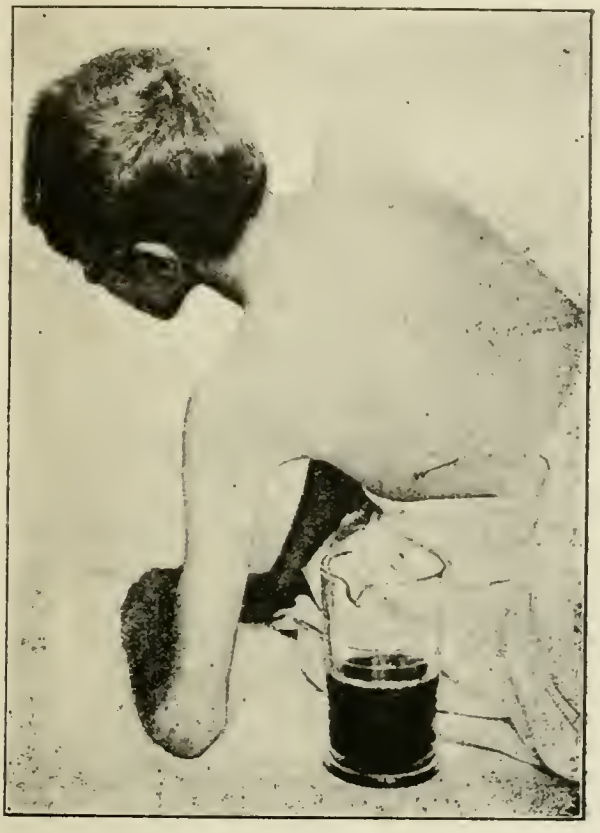
Poisoning by Bichloride in the Vagina.—J. R. Hopkins reports a case of a woman who died from bichloride poisoning as the result of placing one tablet of 7.3 grains in the vagina. The symptoms were local burning, vomiting, diarrhea, and first polyuria, but later anuria. The local burning caused extensive necrosis.—*Denver Medical Times.*

TAPPING THE PLEURAL CAVITY.

By E. M. FOOTE, M.D.,

NEW YORK.

The usual method of procedure for tapping the pleural cavity is to insert an exploring needle, and, if serum escapes, to withdraw the needle, insert at the same place a larger needle or a trocar and aspirate the pleural contents. If, however, an aspirator is not at hand, or it is deemed better not to insert a suction needle, the exploring needle may be utilized for the escape of the fluid. The boy represented in the accompanying illustration had been sick for three weeks with pleurisy with effusion. After cocainization of the skin and pleura, the exploring needle was inserted in the tenth interspace. A clear serum dripped out through it so rapidly that the chest was emptied of 26 oz. in about one-half hour. Toward the end of this period the flow was favored by changes of position and pressure upon the abdomen. There was no reaccumulation of the fluid and the boy made an uneventful recovery.



Aspiration of joints containing fluid may often be successfully performed in the same manner. One thereby avoids the risk of forcibly drawing inflamed surfaces against the point of the needle. Some of the older surgeons objected to the use of suction in aspiration of serous cavities.

130 West Forty-eighth Street.

Thoracic Aneurysm in a Boy.—McNalty reports a case of a boy of 14 admitted to Brompton Hospital for breathlessness and palpitation. He had had scarlet fever at 4, measles at 5, and sore throat at 8. Since then he had had "valvular disease." The boy had a large thoracic aneurysm extending 1½ inches to the right of the sternum and bulging well up into the right neck. The diagnosis was confirmed by the *x*-ray. A point of considerable interest was the presence of an "inverse tracheal tug," by which at each pulsation the trachea was forced upward instead of being pulled down.—*Proceedings of the Royal Society of Medicine.*

MEDICAL RECORD.

A Weekly Journal of Medicine and Surgery.

THE PUBLIC HEALTH AND MARINE-HOSPITAL SERVICE.

THERE are probably few departments under the Federal Government of which the general public knows so little, and to which it owes so much, as the United States Public Health and Marine-Hospital Service. Organized in 1798, primarily for the relief of sick and disabled seamen of the merchant marine and navy, its duties have steadily increased and broadened until the officers of this service have become the chief guardians of the national health, and, if Congress accepts the suggestion of President Taft, it bids fair to become of even greater influence as the foundation stone of the proposed Federal Bureau of Health. The energies of the service are not confined to our own land and our dependencies. They extend to the entire world, for, associated with many of our consulates in seaports the world over are its officers, keeping constant watch on all shipping destined for our ports, ever vigilant that plagues and epidemics may get no foothold in this country. When no epidemics prevail, the members of the service devote their time to the care of seamen and to research; but, when a serious epidemic makes its appearance anywhere, either the local officers, or others especially designated to the duty, are to be found hard at work in combating the disease, preventing its spread, and striving to solve the various problems of etiology, prophylaxis, and cure. While the surgeon of the Army or the Navy may, in the course of his regular duties, be exposed to serious danger in the rare case of war, or occasionally when in tropical service, the members of the Public Health Service are liable at any moment to be ordered into the midst of an epidemic of yellow fever, cholera, smallpox, or plague, diseases which many of them have contracted and to which some have succumbed.

To the surgeon of the Army or the Navy the country owes much, but to the Marine Hospital surgeon it assuredly owes more, for in his constant successful fight against contagious diseases he is keeping in check an enemy capable of far greater devastation than the most successful of human armies. Yet notwithstanding the inestimable services which this corps is rendering the nation, notwithstanding that the risk of life is so great that some insurance companies have refused to issue policies to its members, notwithstanding that the personnel of the service includes some of the most highly trained scientists in the country, men whose work is recognized, and authority accepted wherever the science of hygiene and sanitation is studied, notwithstanding all this, the United States Public Health and Marine Hospital Service is receiving such beggarly support from the Government that its members are becoming discouraged, old officers are resigning their positions, and new ones are enlisted only with the greatest difficulty. In return for protecting the country against pestilence and plague, and thus saving thousands of lives and millions of dollars, the members of this service are receiving pay below that of surgeons in the other services and on which it is almost impossible to live.

A few years ago the surgeons of the three national medical services received nearly equal pay, but after the Spanish-American War there was a popular demand for an improvement in the personnel of the medical departments of the Army and Navy. To procure this, all salaries were raised so that the members of these branches receive a decent living wage. An effort was made last year to do the same for the Marine-Hospital Service, and Senator Owens introduced a bill which passed the Senate, but did not come to a vote in the House. The bill provided for increase of salaries to place the three services on nearly an equal footing, and for the introduction in the Marine-Hospital Service of a retirement rule by means of which a disabled or superannuated senior officer may be retired on three-quarter pay. This is intended to replace the present system of "waiting orders," by which the older man, although doing no work, still maintains his rank, and designating his duties to his next in command allows the latter neither the title nor the pay which the work is supposed to command. Such a provision would tend to make promotion, which for a number of years has been practically stagnant, more rapid, and would furthermore go far to remove the present entirely justifiable feeling of dissatisfaction in the corps.

The passage of the Owens bill when it again is brought forward would place the Marine-Hospital Service on an equal footing, both in prestige and in salary with the medical corps of the Army and of the Navy. Its previous record and present work certainly entitle it to such a position. The passage of the bill would remove the spirit of discouragement now prevalent among its officers, would refill its depleting ranks, and the efficiency of the service would be increased; the nation would be better protected, and the Marine-Hospital Service would be in a healthier, stronger condition to take on the duties of the Federal Bureau of Health when the time comes. As a profession, we are proud of the position the Marine-Hospital Service has won for itself under the able administration of Surgeon-General Wyman, and it would be nothing less than a disaster should this most important bureau in the National Government be crippled through the niggardliness of Congress or its indifference to the welfare of those who have the health of the country in their keeping.

TREATMENT OF EPILEPSY WITH CALCIUM SALTS.

Calcium metabolism has been exciting a good deal of attention recently, and as Halford points out the results of recent observations and experiments on the physiology of the female genital organs may well lead us to think that calcium metabolism will become a prominent feature in the physiology and pathology of the future. According to the *Lancet* of January 8, 1910, the discovery of the action of calcium salts in the treatment of epilepsy is due to the researches of a succession of Italian investigators. For example, Sabbatani found that soaking the cortex in a solution of calcium chloride diminishes its excitability, while such salts as sodium oxalate or citrate have an opposite effect, and he decided that a lack of calcium salts in the circulation, balks largely as a factor, if not in the causation, at least, in the continuance, of the malady. Besta came to conclusions of a similar nature. Mr. Arthur Littlejohn reported in the *Lancet*, May 15, 1909, that he had employed calcium salts with success in the treatment of a case of epilepsy. The patient in question was disoriented, incoherent, noisy, and spiteful, and was having fits of an aggravated petit mal type three to five times every 24 hours. After the administration of 15 grains of calcium lactate three times per day, her fits were abolished and her mental condition was very noticeably improved. However, the evidence in favor of calcium salts in the treatment of epilepsy is still conflicting.

Julius Donath, physician to the Nervous Section of the St. Stephen Hospital in Budapest, has published recently in *Epilepsia* a series of cases in which the administration of calcium salts appears to have exerted no favorable effects. Large, even heroic doses of calcium chloride were given in four cases with no beneficial effects, and in the other cases with but a slight diminishing influence. Indeed, the employment of calcium salts in epilepsy has not as yet passed the experimental stage, and as a matter of fact, it is not definitely known whether the abnormal chemical changes of the blood observed in epilepsy are really cause or effect. Some other investigators have not been able to discover the diminution in the coagulability of the blood noted by Besta, he having found that in 37 out of 45 cases of epilepsy, the coagulability of the blood is diminished compared with the normal. Nevertheless, Perugia, in *Il Morgagni* for October, 1908, corroborated Besta's findings in 36 cases of true epilepsy, but curious to state, while affirming that the administration of calcium salts increased the coagulability of the blood of his cases, it did not influence either the number of the frequency of the attacks.

It is, of course, a matter of common knowledge that fairly often in protracted cases of epilepsy the bromide treatment is of no avail, and although the employment of calcium has not been attended by definitely favorable results, the reports of its helpful effects should ensure for the method a wide and careful trial. At any rate, in cases of severe petit mal its administration may be recommended.

The Position of the Apex Beat in Children.

The relation of the size and weight of the heart to that of the body as a whole at the various periods of life has been the subject of study by anatomists on many occasions and the changes in this ratio at different ages are fairly well understood. From the clinical side of the question, however, the subject has been less carefully worked out, and not only students, but practitioners also, in examining the chest of a young child are apt, especially in the presence of a cardiac murmur, to fall into error in considering the question of the presence or absence of hypertrophy of the heart. For this reason a recent study of the position of the apex beat in 500 children made by Stewart and reported in *The British Journal of Children's Diseases* for December, 1909, is of considerable value to the pediatrist. The children were taken consecutively, only those showing evidence of cardiac or pulmonary disease or other malady which could displace the position of the heart being excluded. They were examined in the erect posture, and the relation of the apex beat to the left nipple in the fifth intercostal space was noted. Owing to the fact that the nipple in the young child is placed relatively more laterally than in the adult, the nipple line does not coincide exactly with the imaginary mammary line drawn from the middle of the clavicle, but as the latter is difficult to obtain in the child, the former was taken as the guide. By tabulating the results in three classes, namely those in which the apex beat was outside, on, or inside the nipple line, fairly constant and interesting results were obtained. Under two years of age 66 per cent. were distinctly outside of the nipple, 33 per cent. directly below it, and but 1 per cent. inside. By the age of three years, however, the apex beat had moved in decidedly, and from then until eight years of age its normal position, or at least its position in 80 per cent. of the children examined, was in the nipple line itself, while the proportion of those in which it was outside steadily sank from 20 to 5 per cent., and the cases with the apex inside of the nipple as regularly rose from *nil* to 15 per cent. After the age of eight years the cases with the apex outside became distinct rarities, while the number in which the adult position was found uniformly increased, and those in which the apex was in the nipple line proportionally diminished. By ten years the second and third classes of cases were of equal frequency, and at fourteen the adult location was found in two-thirds of all cases. By dividing the cases into these age groups the normal position at any one time is easily remembered, and is a point of no small value in the physical examination of the child's heart.

Plague Infection in Wood Rats.

W. C. Rucker, Passed Assistant Surgeon, United States Public Health and Marine-Hospital Service, who has for some time been engaged in the investigation of plague infection among ground squirrels in California, and who has succeeded in demonstrating that these animals are infected not infrequently, has added recently a fresh link to the chain in the discovery of a wood rat which upon dissection was found to be suffering from bubonic plague. The infection of this wood rat was found by Passed Assistant Surgeon G. W. McCoy, in charge of the laboratory of the service in San Francisco, and was reported by Rucker in Public Health Reports, Jan. 7, 1910. The animal in

question was secured by Rucker from Alameda County, Cal., on Oct. 17, 1909, and despatched to San Francisco for postmortem examination. This species, *Neotoma fascipes,* is fully described by Frank Stephens in "California Mammals," published in 1906. It differs distinctly from the true rat, which is an Old World importation. The wood rat is entirely a New World production and is a member of a genus which includes a large number of species, all inhabiting various districts of California, and some, certain parts of Colorado. Wood rats are chiefly nocturnal in their habits, and are found for the most part along small wooded arrogos in which they build their nests. According to Rucker, the nests are frequently of elaborate design, the interior of which is often arranged in three stories, containing storehouse and living rooms. The storehouse in several instances examined by the writer contained large quantities of the corms of a plant growing in the immediate neighborhood. In certain regions the neotomas store up large quantities of mesquite beans, and these caches are raided annually by the Indians, who use them for food. The animals are not regarded as an economic menace, they do not make their homes in houses, although they will enter deserted houses, they do not exist in the company of the Old World rats, who will always drive them out, and they are easily trapped. As Rucker remarks, it is impossible to draw deductions from the discovery of a single infected animal of a given species, but it is interesting to note that it is being learned gradually that many different species may be infected in nature. The question which will commend itself to the scientifically inquisitive is, how did wood rats become infected? It is stated that they do not, as a rule, come into contact with ground squirrels, although perhaps, this may seem to be the most natural and obvious means of infection. On the other hand, there may be another infected animal with which the wood rat is more closely associated. At any rate, it has been proved that the plague is far more widespread than it was formerly believed to be. The labors of the members of the Public Health and Marine-Hospital Service have been already instrumental in driving the disease from San Francisco, and it appears likely that their further efforts will result not only in eradicating it from the Pacific Slope, but in solving many obscure features in connection with the plague.

Psychoses and Dream States.

In a paper on the mechanism and interpretation of dreams, read recently before the Neurological Section of the Academy of Medicine, Morton Prince of Boston stated that dreams are in reality psychoses or types of delirium, and are characterized by the same general symptoms—if one may speak of a symptom aside from disease. There is a given point at which the various types of hallucinatory phenomena tend to converge with the types of hallucinatory symbolism, but the great complexity of psychical phenomena, together with the usual lack of memory concerning dream states, makes the subject particularly difficult of investigation. But this much is sure: that the relation between dreams and antecedent thought is always a direct and definite one, although the connection may seem very remote, and can be elucidated only by a careful and exhaustive analysis. He does not believe with Freud, that every dream represents the fulfillment of a wish; but rather, that it represents the unfulfillment of a wish or the fulfillment of a fear. One woman mentioned by him always dreamed that she was surrounded by a myriad of cats, and she would usually awake when they seemed to be attacking her or when she was thrown helplessly among them. Under hypnotic influence it was found that in early childhood this woman had been greatly frightened by a pet cat, which had scratched and bitten her, and that the memory of this occasion, although seemingly buried deep in the jumble of past experiences, nevertheless had a certain psychological coloring which caused it to be resurrected only during unconscious states. Such facts may explain in a measure the curious and apparently utterly illogical statements coming from the lips of those in delirium, but it will always be found that, just as in many hallucinatory states of the insane, the mind is working at a tremendous rate, much faster than the organs of speech can record the ideas, and hence what comes to our ears is simply a mass of words.

News of the Week.

The Physical Condition of New York School Children.—A report of the physical condition of the children attending the New York public schools has been made to the Board of Education by City Superintendent Maxwell. The superintendent's report is based upon examinations of pupils made by physicians assigned by the Board of Health to duty in the public schools. These physicians examined 323,344 children, about half of the total number in the public schools in the last year, and found that less than one-fourth of them had no physical defects. Of the pupils examined it was discovered that 242,048 needed medical or surgical treatment. The nature of the physical defects varied greatly. There were 3,850 children discovered to be suffering from diphtheria, scarlet fever, measles, chicken pox, and mumps. The examinations disclosed 38,329 children suffering from defects of vision and 73,058 from defects of nasal breathing. Defects of hearing numbered 3,471. It was found that 183,869 children had defective teeth. The cases of pediculosis numbered 145,066. Malnutrition was the diagnosis in 11,749 cases, and anemia in 2,408.

"Preventorium Bill" in New Jersey Legislature.—A bill was recently introduced into the New Jersey Legislature, which, if passed, will make the continuance of the Lakewood Preventorium impossible. The bill provides that it shall be unlawful to treat any person for tuberculosis, or to maintain any person for the prevention of tuberculosis in any hospital, sanatorium, preventorium, or other place without the consent in writing of the Board of Health of the State of New Jersey. The law does not apply to care of relatives in private houses, or to inmates of State, county, city, or municipal institutions.

The State Civil Service Commission will hold examinations on February 26, 1910, as follows: First Assistant Physician, Tuberculosis Hospital, Raybrook, $1,500 and maintenance; Optical Surgeon (Optometrist), Soldiers' and Sailors' Home, Bath, $300; Trained Nurse, $420 to $600. The last day for filing applications for the above positions is February 19. For detailed circular and application blank, address State Civil Service Commission, Albany, N. Y.

New Infirmary for Cornell.—Announcement has been made that Cornell University is to have a new infirmary at Ithaca, which will be twice as large as the present building, to accommodate the rapid increase in the number of students. The new building will be approximately 140 feet in length and 50 feet in width. It will be of hollow terra cotta block and plaster construction. It will be thoroughly equipped as a modern hospital.

The International Commission on Control of Tuberculosis of Domestic Animals held its first session in Buffalo recently. The following resolutions were adopted: (1) That general compulsory tuberculin test and slaughter is impractical and should be dropped from further consideration. (2) That voluntary testing for owners as a general State policy should be retained, provided it be recognized for what it really is; *i. e.* a very efficient means of public education and as serving somewhat to keep further spread of tuberculosis among domestic animals in check. (3) It was unanimously agreed, recognizing fully its limitations, that we can and should accept the tuberculin test under certain conditions as a basis of suitable control legislation. Dr. J. G. Rutherford of Ottawa was elected chairman of the Commission and Dr. M. H. Reynolds of the University of Minnesota secretary.

The Alumni Association of the Lying-In Hospital of the City of New York will hold its next meeting Tuesday, February 8, 1910, at the Harvard Club, 27 W. Forty-fourth street, at 8:30 P.M.

"Medical Review of Reviews."—Beginning with the January, 1910, issue, this journal will be edited by Dr. William J. Robinson of this city. The editorial offices have been removed to 12 Mt. Morris Park W., New York City.

The "Journal of the Southern Medical Association" has gone out of existence with the completion of Volume VI, December, 1909. The reason for the discontinuance of the journal was that it being the official organ of the Association, and given free to all its members, the Federal postal authorities would not admit it to the mails as second-class matter.

The American Society of Sanitary and Moral Prophylaxis will hold a joint meeting with the New York Association of Biology Teachers on Thursday, February 10, at 8:30 P.M., at the New York Academy of Medicine. The general subject for discussion will be The Teaching of Sex-hygiene Along Biological Lines.

The Ninth Congress of the German Society for Orthopedic Surgery will be held in Berlin in the Langenleckhaus, Ziegelstrasse 10/11, beginning on Thursday, March 29, 1910, at 9 A.M., the day previous to the meeting of the German Surgical Society. Titles and short abstracts of papers should be sent before February 15, 1910, to the chairman, Dr. Georg Joachimsthal, Genthiner-Strasse 16, Berlin, Germany.

The Connecticut Society of Alienists met on January 13, at New Haven, for their annual session. The following officers were elected: *President*, Dr. D. W. MacFarland of Greens Farms; *Secretary*, Dr. Alvin D. Wadsworth of South Norwalk; *Treasurer*, Dr. Frederick D. Ruland of Westport. The *Members* of the *Executive Committee* are Dr. H. M. Pollock of Norwich, Dr. Henry R. Noble of Middletown, Dr. C. W. Jackson of Watertown, Dr. Amos J. Givens of Stamford, and Dr. John L. Buel of Litchfield.

Medicolegal Society of Philadelphia.—At the annual meeting held January 25 the following officers were elected for the ensuing year: *President*, Dr. Samuel P. Gerhard; *Vice-Presidents*, Dr. Lambert Ott and Dr. Clarence Loeb; *Secretary*, Dr. Wm. T. Hamilton; *Treasurer*, Dr. G. M. D. Peltz.

Medical Club of Philadelphia.—At the annual meeting, held January 21, the following officers were elected for the ensuing year: *President*, Dr. James B. Walker; *Vice-Presidents*, Dr. William L. Rodman and Dr. S. Lewis Zieglar; *Secretary*, Dr. J. Gurney Taylor; *Treasurer*, Dr. Lewis H. Adler, Jr.; *Governor*, Dr. George A. Knowles; *Directors*, Drs. Ross V. Patterson, Frank C. Hammond, McCluney Radcliffe, J. T. Rugh, and C. A. E. Codman.

Northern Medical Association of Philadelphia.—At the annual meeting held January 14 the following officers were elected for the ensuing year: *President*, Dr. William R. Brady; *Vice-Presidents*, Drs. Thomas Shriner and L. Latchford; *Secretary*, Dr. P. F. Brehmer; *Treasurer*, Dr. John W. Millick.

Philadelphia County Medical Society.—At a stated meeting held January 19 the following officers were elected for the ensuing year: *President*, Dr. Henry Leffmann; *Vice-Presidents*, Dr. William S. Newcomet and Dr. G. Morton Illman; *Associate Vice-Presidents*, Drs. Samuel Wolfe, R. O. Kevin, C. B. Longenecker, J. J. Gilbride, E. E. Keiser, Frank B. Gummey; *Secretary*, Dr. William S. Wray; *Assistant Secretary*, Dr. A. R. Craig; *Treasurer*, Dr. Collier L. Bower; *Censor*, Dr. Judson Daland.

Northampton County (Pa.) Medical Society.—At the annual meeting held at Easton, on January 21, the following officers were elected for the ensuing year: *President*, Dr. Charles E. Beck of Portland; *Vice-Presidents*, Drs. J. Edgar Fretz of Easton and L. C. Babcock of Bethlehem; *Secretary*, Dr. W. D. Chace of Bethlehem; *Corresponding Secretary*, Dr. N. W. Reichard of Bangor; *Treasurer*, Dr. Clinton G. Stoffel of Pen Argyl; *Reporter*, Dr. B. Rush Field of Easton; *Censors*, Dr. D. H. Keller of Bangor, Dr. C. T. Zulick of Easton, and Dr. E. D. Schnabel of Bethlehem.

The Cass County (Ind.) Medical Society meeting at Logansport recently elected the following officers: *President*, Dr. R. E. Troutman; *Vice-President*, Dr. A. W. Tucker; *Secretary*, Dr. G. D. Miller.

The Franklin County (Me.) Medical Society has elected the following officers for 1910: *President*, Dr. A. G. Howard; *Vice-President*, Dr. C. W. Bell; *Secretary*, Dr. A. S. Pratt; *Treasurer*, Dr. J. W. Perkins; *Censors*, Drs. E. L. Pennell and B. F. Makepeace.

The Fulton County (Ga.) Medical Society held its annual meeting in Atlanta January 6, 1910, and elected the following officers: *President*, Dr. J. R. Simpson; *Vice-President*, Dr. E. G. Ballenger; *Secretary*, Dr. R. R. Daly.

The Miller's River Medical Society met at Athol, Mass., January 1, 1910, and elected officers as follows: *President*, Dr. G. R. Johnson of Templeton; *Vice-President, Secretary and Treasurer*, Dr. George J. Bassow, of Athol.

The Hartford (Conn.) Medical Society held its annual meeting recently and presented a loving cup to Dr. Horace S. Fuller. The following officers were elected: *President*, Dr. E. K. Root; *Vice-President*, Dr. M. M. Johnson; *Secretary*, Dr. A.

R. Keith; *Assistant Secretary*, Dr. E. A. Hotchkiss; *Treasurer*, Dr. G. K. Welch; *Librarian*, Dr. W. R. Steiner; *Board of Trustees*, Dr. G. P. Davis, Dr. A. E. Abrams, Dr. E. K. Root; *Board of Censors*, Dr. J. H. Rose, Dr. C. S. Stern, Dr. T. F. Kane.

The Nashau (N. H.) Medical Society met January 6, 1910, and elected the following officers: *President*, Dr. H. L. Smith; *Vice-Presidents*, Dr. W. E. Reed and Dr. Arthur L. Wallace; *Secretary*, Dr. Eva M. Locke; *Treasurer*, Dr. P. J. McLaughlin.

Philadelphia Pediatric Society.—At the annual meeting held January 11, the following officers were elected for the ensuing year: *President*, Dr. C. A. Fife; *Vice-Presidents*, Dr. J. T. Rugh, Dr. Theodore H. Le Boutillier, and Dr. A. Newlin; *Secretary*, Dr. Maurice Ostheimer; *Treasurer*, Dr. Howard Childs Carpenter; *Librarian*, Dr. C. F. Judson.

Obituary Notes.—Dr. Samuel S. Wiltbank, U. S. N., died suddenly of heart disease, on January 25, on the Tredavon River, near Easton, Pa., at the age of 82 years. He was a son of Dr. John Wiltbank, in his day one of the foremost physicians of Philadelphia.

Dr. Thomas H. Wentz died at Philadelphia, on January 29, at the age of 62 years. He was graduated from Jefferson Medical College in the class of 1874.

Dr. Lewis L. Shaw died at Medford, N. J., on January 20, at the age of 67 years. He was graduated from the medical department of the University of Pennsylvania in the class of 1864. He was at one time President of the Burlington County Medical Society, and from 1866 to 1867 a member of the State House of Assembly. At the time of his death he was Chairman of the Township Committee and a member of the local Board of Health.

Dr. [illegible], N. Y., died at his home, January [illegible], of septicemia contracted during [illegible]. He was a graduate of the [illegible] in 1885.

Dr. [illegible], Mich., died January [illegible], 1910, [illegible]. Haze was one of the old[illegible] Wisconsin. He had several [illegible] State Legislature, and in [illegible].

Dr. [illegible] New York died at his home, [illegible] years. He was educated [illegible] Hospital, Paris, and Munich, graduating [illegible] from the latter. Dr. Miranda was [illegible] Medical Society of the County of New [illegible], the New York State Medical Association [illegible] New York Academy of Medicine. [illegible] Dr. Miranda was treasurer of the [illegible] Sciences.

Dr. [illegible] Tex., died at his home, January [illegible] 62 years. He was a graduate of the Bellevue Hospital Medical College in 1881, and was a member of the El Paso County Medical Society and the State Medical Association of Texas.

Dr. W. [illegible] Abbeville, Va., died at his home, January 12, 1910, [illegible] years. He was a graduate of the Medical Department of Tulane University. Dr. Lee was a veteran of the Confederate Army. He retired from practice several years ago.

Dr. Sidney Crooks McClure of Jeffersonville, Ind., died at the Mercy Hospital, in Louisville, January 17, 1910, aged 59 years. He was a graduate of the Hospital College of Medicine in Louisville in 1878.

Dr. James Reed of Rockwood, Mich., died at his home, January 18, 1910, aged 70 years. Dr. Reed was a graduate of the Medical College of Ohio in 1866, a veteran of the Civil War, and a member of the Wayne County Medical Society and the Michigan State Medical Society.

Dr. Nelson Reynolds of Milwaukee died January 20, 1910, aged 35 years. He was a graduate of the Milwaukee Medical College in 1898.

Dr. J. Shotwell Smith of Wheeling, W. Va., died at the Haskins Hospital, January 19, 1910. He was a graduate of the Medical Department of the University of Maryland, in 1891, and was a member of the Ohio County Medical Society, the West Virginia State Medical Society, and the American Medical Association.

Correspondence.

THE SUGGESTIONS FOR REFORMS IN THE A. M. A. EMBODIED IN THE RECENT RESOLUTIONS PASSED BY THE CHICAGO MEDICAL SOCIETY.

To the Editor of the Medical Record:

Sir:—The resolutions recently passed by the Chicago Medical Society recommending to the A. M. A. certain reforms for which I have been long contending mark the beginning of a new and more democratic era in our great national organization. Certain faults in the politics of the association are so evident and glaring that it would be surprising that they should have so long continued, were it not for the fact that one of those faults is the removal of the direct ballot from the membership, which in itself prevents the remedying of the other evils. The resolutions did not comprise the suggestion of elections by membership ballot in the A. M. A., as, in my opinion, they should have done. In a body as large and important as the A. M. A., with enormous political, business, and financial interests, the ballot is the only protection for membership rights. American citizens do not like to be led like a lot of sheep, with no opinions of their own, and no way of expressing them if they did possess them.

The politics of the A. M. A. are somewhat anomalous. When reduced to its ultimate, the fairness, legality, and honesty of elections revolve around the voting unit. Tracing the politics of the A. M. A. backward from its House of Delegates, we come to the State Society with its House of Delegates. As these delegates are not elected by the State Society, but by the Councils of the District or County Societies, we have as yet no voting unit. Following medical politics down along the line, we come to the Council of the local society. The members of this Council are elected by the membership of the local society. Inquiring into the personnel of the local society, we find that it comprises both members and nonmembers of the A. M. A. The members of the A. M. A. have paid ten dollars per year for membership privileges which, so far as the elective franchise is concerned, are enjoyed by nonmembers for from three to five dollars per year. Whether the elections in the A. M. A. since reorganization would stand the test of legality or not is at least an open question. The open ballot in the A. M. A. is the only solution of the problem, for the local and State societies would hardly dare adopt as a qualification for membership forced membership in the A. M. A. The members of the A. M. A. will one day have to choose between the present farcical system and the open ballot. The latter is the only feasible plan for obtaining autonomy and membership rights.

The members of the local and State societies are deprived of their rights, and their organizations are deprived of autonomy in quite another way, viz., by the dominance of high officials of the A. M. A. in the local and State societies. Take, for example, the Chicago Medical Society and the Illinois State Society. The chairman of the board of trustees is a councillor in the former and a delegate to the latter. He is also a delegate to the A. M. A. The associate editor and assistant secretary of the A. M. A.—a salaried employee of the association—is a councillor in the Chicago Med-

ical Society and a delegate to the State society. The treasurer of the A. M. A. has served simultaneously as councillor, State delegate, national delegate, and treasurer. In California we have a trustee of the A. M. A. serving as delegate to the A. M. A. and editor of the State journal. Whether he is serving also as a member of his local Council and a delegate to his State society I do not know, but it is safe to infer that he is—or could be if he so desired, which latter is the key to the entire situation. And Chicago, Illinois, San Francisco, and California are merely pertinent illustrations of what prevails the country over.

It is unnecessary for me to repeat here the evidence I have elsewhere published regarding the danger under present conditions of the abuse of official power in the A. M. A. I will, however, call attention to one of the most powerful weapons of oppression at the command of certain officials, viz., the possibility of an interpretation of the by-laws of the A. M. A. which may be used to force a member who has moved from the locality in which he originally joined the association to affiliate with the subsidiary society in his new location.

The case of Dr. Howard Crutcher, of Roswell, N. M., is an example of this. His membership cross was omitted from the last A. M. A. directory because he had not joined the Chaves County Society. As Dr. Crutcher would not join the local society if he could, and could not if he would, he was placed in a rather peculiar position. As his dues are paid in the Chicago Medical and Illinois State societies, and also in the A. M. A., the officers of the association are in a still more peculiar situation, the more especially as there is nothing in the constitution and by-laws of the A. M. A. which compels Dr. Crutcher to join a new local society in order to retain his membership in the A. M. A. Obviously, if a member in good standing of the A. M. A. is compelled to join a new local society on removal to a new location a membership transfer should be given him, the acceptance of which should be mandatory on the local body. It would be interesting to observe the attitude of a local society that should be compelled, willy nilly, to receive a man who happened to be *persona non grata*. It requires very little reflection to comprehend that we have here a reef in the course of the good ship "reorganization" over the erstwhile beautiful sea of political theory. I have elsewhere compared to a political "club" the requirement that a physician must become a member of his local and State societies in order to join the A. M. A. Long ago I predicted that sooner or later the political power conferred by this provision would be abused. This prediction, it would appear, has been verified.

The recommendation by the Chicago Medical Society of an increase in the number of trustees in the A. M. A. is without point unless some specific object is set forth. The increase in the number of trustees should consist of the addition of at least two local trustees. The business and policies of the A. M. A. are entirely too weighty for one man to handle, and I doubt not the chairman of the board would be glad to have his weighty burdens and serious responsibilities divided. It has been stated that the country at large would object to a further aggregation of officials at the "central station" of the A. M. A. In reply I would ask, which is the more democratic, a division of labor and responsibility among three or more, or a concentration of power, privilege, and responsibility in the hands of a single individual? The association must have headquarters somewhere, hence the question is, how best to conduct its business and policies at that point.

An addition which might with advantage have been made to the Chicago Medical Society's resolutions is the suggestion of a provision for either an itemized yearly account of the business of the A. M. A., or, if this plan should be found to be impracticable, the yearly appointment of a special nonofficial committee to examine and report upon the business affairs of the association. Some plan certainly should be provided by which the membership of the A. M. A. would be taken more intimately into the confidence of the official body. This would do much to allay the present natural unrest among the rank and file. Another reform the suggestion of which would have been popular with those who believe in conducting the association along purely democratic lines is the nomination of candidates for various high offices by petition. This, if adopted, would relieve the annual elections of their present "cut and dried" quality. It works well in the Chicago Medical Society, why not in the A. M. A.? This much may be said of the physician, viz., impractical though he may be in the every day affairs of life, he has deep down in his heart as much American pride of citizenship as has the average man. This being true, the majority of officially disinterested members of the A. M. A. must needs in self-respect and regard for their individual rights demand many reforms in the organization.

CHICAGO. G. FRANK LYDSTON, M.D.

OUR LONDON LETTER.

(From Our Regular Correspondent.)

MEDICAL CANDIDATES AT THE GENERAL ELECTION—ULCERATION OF THE DUODENUM—A CENTENARIAN DOCTOR—LEGACIES—OBITUARY.

LONDON, January 14, 1910.

THE impending general election—the first polls take place to-morrow—has diverted attention from strictly medical questions to a remarkable extent. The professional journals are supposed to be quite neutral, but some of the writers manage to indicate their prepossessions. Medical questions have little influence on politics in ordinary times, so that on this occasion, which all parties declare to be big as to the fate of the country, nothing is to be expected from party politicians—promises, of course, excepted, which cost little and are usually of the pie-crust kind. Among the candidates for Parliament there are twenty-four qualified medical men, but only two or three are practising. Sir Robert Finlay, who has been Solicitor-General and Attorney-General, is M.D. of Edinburgh, but long ago forsook medicine for the law and attained the highest positions at the English bar. He is a candidate for his university, and claims the support of conservative doctors as having medical interests at heart, being himself a doctor of medicine, and his father and brother also members of the profession. In opposition to him on the other side of politics is Dr. A. R. Simpson, for thirty-five years professor of obstetrics in the University of Edinburgh and for five years dean of the medical faculty. The glamor of his uncle's name will probably secure him many medical votes from men who pay little attention to political subjects, while graduates of his own party are, of course, pushing his candidature. Sir G. Polland and Sir B. J. Price long ago gave up medicine for the law. Dr. Lunn, best known as the organizer of a tourist business, began his career as a medical missionary. Sir G. S. Robertson began in the Indian medical service, and was made a political officer on the wild Western frontier. Sir William Collins, the ophthalmic surgeon, has already served in Parliament. So has Sir W. Foster of Birmingham. Among other medical candidates are: Dr. C. Addison, F.R.C.S., lecturer on anatomy at Bart's; Dr. Moon, M.D. Oxon., F.R.C.P.; Dr. Permewan, the Liverpool laryngologist; Surgeon-Major Evatt.

Dr. Moon's candidature is of special interest to the profession, as so many doctors reside in the district, East Marylebone, which Lord Robert Cecil has had to abandon on account of his advocacy of free trade and his somewhat crooked conduct. Unable to force himself on the constituency, he has tried to cause a split in his own party. Dr. Moon expects to profit by this split in the other camp. Lord Robert Cecil persuaded Lord Charles Berresford to offer himself, but as soon as he saw how matters stood the bluff old admiral refused to go on. Now Lord Robert and a few other lords have got another person, a local tradesman, to carry on the split. These nobles are doing disservice to their order. One of them made a statement about the original candidate, who has demanded a retraction of the "malicious lie" on three occasions, but his lordship is silent about it. I am afraid if Dr. Moon gets in he will not have the influence he should have on professional matters, for it will be known he only crept in through a split in the opposite camp.

Harley Street is vexing itself on this and other points—most of all, perhaps, that Sir D. Powell has thrown himself actively into the campaign—not as a matter of principle, but only to please a personal friend.

Turning to clinical subjects, perhaps ulcer of the duodenum has been most talked about during the last few months, and on the 14th ult. it was discussed at a joint meeting of the two sections of medicine and surgery at the Royal Society of Medicine. Mr. Moyni-

han came from Liverpool to open the debate with the story of his great success by surgical measures and a statement of the views he holds. His cases up to November numbered 186, of which four were fatal. Hemorrhage had occurred in 35 per cent. In the early cases there were three examples of tetany from stenosis dilatation, and eleven were operated on for perforation. In the last five years 116 consecutive operations were performed without any death. Subsequent histories to date showed that only eighteen could be said not to have been cured. The operations included excision of the ulcer, resection of the affected portion of the duodenum, and gastroenterostomy. Mr. Moynihan's invariable practice now is to infold the ulcer, obliterating the lumen of the pylorus, and to unite the jejunum to the stomach without a loop. Considering the nature of the lesion, it seems only natural that a surgeon should plead for early operation, and this Mr. Moynihan does—a practice which tends to prevent complications, though he has not found them as common as might be expected. Nevertheless, hemorrhage may be an early sign, and so may copious and intractable vomiting. But the onset is more often marked by digestive disturbances, from two to four hours after food, increasing until the next meal, which seems to relieve it—hunger pain, as it has been called—distension of the stomach, loss of appetite (this by no means constant), and in some cases occasional vomiting. The pain is relieved by a dose of sodium bicarbonate; so it is by a little food—say a biscuit—or even a drink of water. Patients soon discover those things and that there is a certain periodicity in their attacks. Acidity is a pretty constant complaint, which may be due to hyperchlorhydria or may not. When it does, Mr. Moynihan considers it as a diagnostic symptom of duodenal ulcer. He admits that in a first, or even a second attack, medical treatment continued long enough may perhaps be successful, but chronic ulcer as a rule must be treated surgically. The picture of the disease he gives is, in fact, that of late indigestion occurring in distinct attacks, and he is emphatic on the certainty of diagnosis. On one occasion he said a man came into his consulting room with so characteristic a countenance that he felt sure he had an ulcer, and on asking him if he suffered from indigestion was answered "for years," and an accurate history was added which confirmed the first impression. It is not to be supposed he would rely on or encourage such an impression being called a diagnosis. Indeed one has seen just what he describes with all the symptoms in certain cases we can only call indigestion, and which, after many attacks, have completely recovered.

In the discussion that followed Sir Lauder Brunton said he had tried to cause ulcers in the stomach and bowels of animals by cutting off temporally the blood supply, but always without success. The time relation of food to onset indicated the duodenum as the point of the lesion, but gave no clue to its nature. Mixed carbonates of soda, lime, and magnesia would relieve, and if they did not he doubted the existence of an ulcer in the case. In some cases it was difficult to differentiate gallstones and duodenal ulcer. He advised rest in bed, warmth, and careful diet, and if recurrence followed surgery was called for.

Mr. Eve agreed with Mr. Moynihan that a second attack demanded operation. Gastroenterostomy was satisfactory if the pylorus were obliterated. If not, it was hardly a cure. The ulcers were often multiple, so excision was not an appropriate method; they were not easy to see, and too much stress was often laid on peritoneal changes as indicating their existence. Digital examination of the mucosa was the only certain means in some cases of being sure of the presence or absence of ulceration. Of thirty cases diagnosed by physicians of repute he had operated on twenty-one, and ulceration was not present in twelve. This experience seems to contrast distinctly with that of Mr. Moynihan, who says he has always succeeded in finding the ulcer and demonstrating it to his assistants. However, Mr. Eve admitted that the symptoms are fairly definite, but held that there are exceptions.

Dr. Hale White mentioned some statistics from which he thought there had been an increase of late years in cases of ulcer. He further referred to the difference between in-patients and others in regard to severity of symptoms and the stage at which seen. He said local tenderness and rigidity of the right rectus was rather a constant feature and might render the diagnosis from other lesions difficult.

Mr. Waterhouse referred to the differences between hospital or private practice. He found duodenal ulcers always palpable even if not visible. He had had cases in children. He found the ulcers multiple in 25 per cent., and therefore did not favor excision. He had sometimes found it difficult to decide between gastric and duodenal ulceration, and in such case he had often found both present. There was often occult blood in the stools when melena did not appear. He did not find hyperchlorhydria generally. He held gastroenterostomy to be the all-sufficient and only proper treatment and that every case after a second attack should be submitted to operation.

Yesterday at the meeting of the Council of the College of Surgeons the secretary made the interesting announcement that Dr. Edgar Jones, J.P., who became a member in 1834, had attained the age of one hundred years, was in excellent health for his age, and can read without glasses. Dr. Jones has been a magistrate for his county (Essex) above fifty years, and until the last year or so a regular attendant at the sittings of the bench. In his time he punted and played cricket. When over sixty he climbed Snowden, and when over eighty he played tennis. The president was requested to convey to him the congratulations of the Council.

Sir Alfred Jones left personal estate in England estimated at £446,750. After certain bequests and subject to a power to carry on any business of his for ten years, he gives all the residue of his estate upon trust for such charitable purposes and objects in England or any British possession on the West Coast of Africa as his trustees in their absolute discretion may think fit. For the guidance of his trustees he indicates some such purposes, mentioning specially original research of all kinds into the causes of disease on the West Coast of Africa.

The late Mr. Clutton's estate has been proved at £46,170. Subject to other legacies, he has left a contingent reversion to St. Thomas's Hospital Medical School.

Surgeon-General C. D. Madden died on the 5th inst. in his seventy-seventh year. He entered the army in 1854, served in the Crimean War in 1855, for which he received the medal and clasp, as well as the Turkish medal. He was next in the Indian mutiny with the light infantry. Throughout the Abyssinian campaign he was Surgeon to the Fourth King's Own, and was mentioned in dispatches. In 1896 he was made C.B., in 1897 received the Diamond Jubilee Medal, and in 1902 the Coronation Medal. He was also Honorary Surgeon to the King.

Dr. J. C. F. Naumann, who died at Wiesbaden, was educated in London and Lausanne. He took the double qualification of the colleges in 1887-1888, afterward the M.D., Brussels, and in 1908 the Membership of the London College of Physicians. He had been physician to the Italian Hospital in London, and was a chevalier of the Order of the Crown of Italy.

Lieutenant-Colonel and Honorable Brigade Surgeon-General Campbell Melliss Douglas, M.D., V.C., has also died. He was awarded V.C. for his conspicuous bravery, which saved the lives of seventeen officers and men in an expedition to the Little Omdurman Island.

OUR BERLIN LETTER.

(From Our Regular Correspondent.)

INSTITUTE FOR MEDICAL MISSIONARIES—ORGANIZATION OF CHARITY IN BERLIN—THE EFFECT OF TOBACCO SMOKE ON THE GASTRIC SECRETION—X-RAY EXAMINATION OF THE URINARY TRACT.

BERLIN, December 15, 1909.

THERE has recently been organized in Germany an institute for medical missionaries. It is an incontestable fact that there exists in the colonies a paucity of physicians. The physicians are needed, not only for the medical care of the Germans working there, but also for the general dissemination and promulgation of hygienic doctrines. This is most necessary among the natives, and among them the efforts bear the best fruit. In the institute the preparation of the physician is to be improved by special courses in tropical medicine. Research institution for tropical diseases and hygiene and a hospital are to be associated with the institute. These missionaries and missionary nurses will, as far as possible, be trained medically. The nurses will receive especial training in midwifery. The location of the institute is at Tubingen in Würtemberg, and the

Tubingen medical faculty has taken on the task of the teaching.

During the last few days there have appeared in the Berlin daily papers a series of articles which, with reason, strongly recommend a unification of the various charitable institutions for the care of the sick. The exciting cause of these has been a case in court. A poor, ill, working woman went to a charity physician with her seriously ill child. The physician recommended more sustaining food, and the mother, who was absolutely without means, forged a signature in order to obtain good milk and was sentenced for the crime. This attracted much attention, occurring just at the season of charity and celebration. The woman could assuredly have obtained enough milk had she gone to the proper place for it. There are in Berlin a series of institutions for the care of infants and sufferers from cancer, tuberculosis, and alcoholism, and a great number of charity regulations, but the general public knows nothing of them. The formation of a central office is a crying need, which will soon be realized. The idea is the formation in Berlin of a great organized bureau of information for all health matters.

In the Medical Society Skaller spoke of the occurrence and treatment of gastric hypersecretion among chronic smokers. He has carried out some experiments on dogs to study the very common and extreme gastric hyperacidity found in habitual smokers. He injected into the animals water through which tobacco smoke had been sucked and found that nausea and increase of gastric secretion followed. The latter occurred also when the former was absent. One must, therefore, recognize a lasting secretion brought about by a general intoxication of the organism. If the animals were inoculated with 0.002 gm. of nicotine, the same symptoms appeared as followed the smoke-saturated water. If the water was impregnated with nicotine-free cigar smoke, no toxic symptoms followed. If the secretory nerves were paralyzed with atropine and the nicotine injected, the hypersecretion did not occur. The common emaciation seen among smokers may be caused by the general intoxication as well as by the hypersecretion. Atropine is the best medicament in the treatment of this disease of smokers; in mild cases alkalis are sufficient. The rational therapy is to forbid smoking, at least the "wet" or "cold smokes" and smoking of the end of the stub.

In the Society of Internal Medicine a paper has been read upon the present status of *x*-ray examinations of the urinary apparatus for concretions. The author called attention to the difficulty in taking *x*-ray pictures of the kidneys. This was due to the fact that the atomic weight of the kidneys varied but little from that of the surrounding tissues. In spite of this it was often possible to demonstrate a kidney on the plate. The conditions are different in the case of kidney stones. Oxalate, urate, and uric acid stones are in increasing proportion easy to photograph. One must know, however, that it is easy to transilluminate the urates. In 1 per cent. of cases at operation a stone is found which cast no shadow. The author advised strongly that care be taken in interpreting indefinite shadows. In 2 per cent. of the cases at operation no stone is found, whereas the plate showed a suspicious shadow. During the last four years the author had prepared 1,774 radiographs of kidneys and ureters, of which 321 had shown suspicious shadows on the plates—143 times in the kidneys of males and 109 times in females—while stone in the ureter was shown 41 times in men and 28 times in women. Often the observer must underexpose his plate in order to bring out a stone easily transilluminated. By a series of lantern slides the author demonstrated the position, form, and number of the stones. Whereas, by the usual methods it is possible to examine but one kidney or ureter, by the author's method he is able to examine both ureters, both kidneys, and the bladder on a single plate 40x50 cm. In the diagnosis of ureter and kidney stones one must beware of the so-called "pelvic flakes." The author praised the value of the cystoscope, but believed that the *x*-ray gave a simple and easy method of determining the number and the size of cystic calculi. In conclusion he advised against depending entirely upon the *x*-rays and recommended the use also of all the common and well-known methods of examination.

The approximate cost of tuberculosis to the people of Chicago during the year 1908 was $23,635,000.

Progress of Medical Science.

Boston Medical and Surgical Journal, January 20, 1910.

The Strength of the Uterine Scar After Cesarean Section; An Experimental and Clinical Study.—N. R. Mason and J. T. Williams have performed a large amount of experimental work on this subject and reach the conclusions given below. An interesting portion of their work relates to 21 cases of rupture of the human uterus. Overdistention of the organ, weakening of the scar by subsequent implantation on it of the placenta, and its imperfect consolidation due to its location, suture of the placental site, infection of the uterine wound, improper suture material and imperfect methods of suture all conduce to the accident of weakening of the scar. The conclusions are as follows: a carefully sutured and well-united scar will withstand any strain which can be endured by the uterine muscle. Rupture of a cesarean scar is always secondary to unusual weakness of the scar dependent upon imperfect consolidation. The most frequent cause of imperfect consolidation is placing the deep stitches too far apart or not including the entire thickness of the uterine muscle. Location of the incision and suture of the placental site probably do not affect the strength of the scar. Infection in certain instances plays a very important part in causing weakness of the cicatrix. Catgut as a suture material is open to the objection that there is at least a possibility of the stitches becoming untied and certainly more cases of rupture have occurred after its use than after the use of silk. As a corollary to these conclusions it seems evident that given a uterus which has been sutured with care to include the entire thickness of the muscular portion of the wall in each stitch and to place the deep stitches close together throughout the entire length of the incision, using silk or linen, and where there has been no evidence of sepsis during convalescence, such a uterus may be subjected with safety to distention by a full-term pregnancy or even in the absence of mechanical indication for cesarean section to the strain of labor itself. A short bibliography of the subject closes the paper.

Post-Operative Pneumonia.—E. H. Risley compiles the statistics of the work done in the Massachusetts General Hospital, comprising for his purpose 1,000 laparotomies, including radical cures of hernia. Of the entire number 25 per cent. were done in the presence of pus; 162 were done for acute appendicitis, 153 for chronic appendicitis, 36 were on the stomach, 59 on the kidney, 51 intestinal, 59 were exploratory laparotomies, 200 were pelvic operations, and 226 were done for hernia. Long complications developed in 22. Of these 15 were cases of definite post-operative pneumonia. The author finds this complication most likely to develop in septic cases and in cases in which some trauma has been done, not to the air passages but to the peritoneum. This rather favors the theory that all post-operative lung complications are due to minute emboli rather than to irritation by ether and infection through the air passages. In clean cases the lung complication is not dangerous to life, though these cases seem as nearly liable to the pneumonia as do the septic ones. Previous pneumonic processes do not light up again after ether. Lung complications are more common during the winter months. Flare-ups in old tuberculous cases are fairly common. Much can be done in the way of prophylaxis. The author advises most thorough oral cleanliness, the use of the Trendelenburg position, morphine and atropine subcutaneously half an hour before the anesthetic is taken and the use of the Crile method of administration when practical and in all mouth cases. The causes of the pneumonia are summed up as follows: irritation of the air passages by ether, presence of sepsis, lowered resistance of the patient because of sepsis or shock of operation, trauma to tissues already septic and a foul condition of the mouth and teeth.

The Use of Formalized Cultures of Typhoid Bacilli for the Agglutination Test.—M. E. Morse says that in eight tests a majority showed a positive result with the formalized culture in higher dilutions than with the living. In the remainder there was no essential difference. She believes the formalized cultures to be just as reliable and their reaction a little more delicate. The advantages of the formalized preparations are obvious. Their use secures greater uniformity in method and also by employing the macroscopic method the practitioner who is far from a laboratory and not versed in its methods may perform his own agglutination reactions and thus give another element of precision to his own diagnosis of typhoid. Formalized cultures do away with the necessity of a

stock culture, incubator, etc. The macroscopic method, while requiring a little more serum and a little longer time, does away with the microscope and is much more accurate than the microscopic way. The same arguments apply to ships, army stations, etc. Inasmuch as formalized solutions are more agglutinable than living cultures, it would be of importance to determine their possible use in the precocious diagnosis of typhoid where the ordinary Widal test is negative.

New York Medical Journal, January 22, 1910.

A New Method of Treatment of Phagedenic Chancroid and Chancre by Means of Hot Air.—E. W. Ruggles has applied the hot air method to the treatment of the lesions named in his title and gives reports on a series of cases successfully treated. He believes that the good effects of the remedy are due not merely to the effects of the heat upon circulation and upon the removal of the inflammatory exudates, but also to a certain bactericidal or inhibitory effect upon pathogenic bacteria. He has devised a special oven for generating the hot air. It is portable, simple, and efficient. The air is used at a temperature of from 135° to 140°. Pain is promptly relieved, extension of the process is checked, and attempts at repair are quickly inaugurated. The author is convinced that a large part of the benefit derived is due to the active hyperemia produced by the long-continued heat. The effect upon the bacteria is not only merely inhibitory but bactericidal through the raising of the opsonic index. Full directions are given for the construction of the ovens. They may be heated by kerosene lamps or more safely by electric lamps. A diagram makes the author's ideas perfectly clear and by combining asbestos in the manufacture of the electric ovens the latter may be used with perfect safety.

Appendicitis from the Viewpoint of the Clinician.—M. H. Fussell's views are ascertained from the words of his concluding paragraph. He says, make an accurate diagnosis and operate at once. If a skilled surgeon cannot be obtained or the patient's physical condition will not warrant a diagnosis, put the patient in bed, give him opium, give him little or nothing to eat and put an icebag over the appendix. He regards the main symptoms as pain, local resistance, vomiting, tenderness, leucocytosis, and general abdominal distention. The pulse is usually rapid, and if also weak may be the result of a severe infection or merely result from a mental perturbation. Occasionally a diarrhea or dysentery may usher in the scene, and this fact should never be forgotten. Usually the bowel movements are torpid. Conditions simulating appendicitis are severe colic from acute indigestion, pneumonia, typhoid fever, renal colic, inflammation of the gall-bladder, gastric ulcer, and epididymitis. Illustrative cases are given illustrating difficulties in differential diagnosis. The time for an operation is as soon as a careful diagnosis has been made. The contraindications for an operation are the lack of a skilled surgeon, or some physical condition of the patient, which renders an operation unwise. Personally he has passed through all stages of thought as to operation for appendicitis, from believing that no patient should be operated upon except when there was reason to believe pus existed, to watching the temperature, pulse, blood, and tumor formation, to the radical one of immediate operation, given a proper surgeon and a fit subject. He thoroughly believes that at least three-fourths of the cases of appendicitis would recover if not operated upon, but he knows there are no symptoms that will tell when any case is approaching the danger line until it is extremely dangerous, either to interfere or wait.

The Fungus Diplodia as a Possible Factor in the Etiology of Pellagra.—H. S. Reed discusses the recent outbreak of pellagra in the Southern States and believes that some new organism has gradually invaded the crops of this region. He has made many analyses of the maize there grown and has suggested as the result of his findings that diplodia is the cause. Fungi belonging to this genus have been grown both parasitically and saprophytically upon maize and at present are known to occur over a large part of the maize-producing territory of the country, especially that part in which pellagra or pellagrous diseases have appeared. These fungi, which appear to have become widely distributed more or less simultaneously with the appearance of numerous cases of pellagra, seem on account of these facts fully as probable of significance in the etiology of this disease as those fungi which have for years been associated with mouldy maize. The maize upon which this organism has grown is altered both in physical and chemical composition. Meal infected with diplodia was found toxic to mice. The isolation of proteins soluble in alcohol from diplodia meal yields compounds differing from the same bodies isolated by the same means from sterile meal. The products obtained from diplodia meal appear to resemble in every way the pellagrozein isolated and described by Lombroso. The writer expresses his willingness to undertake the examination of suspected maize or maize products with reference to the finding of fungi in them.

Journal of the American Medical Association, January 22, 1910.

Vaccine Virus.—M. J. Rosenau describes the modern method of producing vaccine virus. The material is usually taken from the vesicles when fully developed, which may be somewhere between the fifth and eight day after the animal has been vaccinated. It should be taken only from typical unbroken vesicles, and is usually obtained by scraping with a curette. The vaccine pulp thus obtained may be purified with glycerin or other substances. Glycerin is best, and is mixed with the pulp in the proportion of from 40 to 50 per cent. This acts as a preservative and antiseptic for the ordinary bacteria. It is impossible to exclude some harmless bacteria from the virus. Strong antiseptic measures being impracticable, we must depend on cleanliness and asepsis in every stage of the production. The old-fashioned dry points are more liable to be contaminated, and the new federal regulation prohibits interstate traffic with them. Manufacturers have made an imitation of these dry points, which furnishes a very convenient method of vaccinating, by putting a drop of glycerinated virus on ivory or glass points hermetically sealed in paraffin or glass. These are safe and satisfactory. All vaccine virus is tested according to modern methods for virulent germs and these tests include animal inoculations. The tests must be satisfactory before the virus is placed on the market. Special tests are made to determine the absence of foot-and-mouth disease and tetanus spores. All establishments manufacturing vaccine virus for the interstate traffic must be under government supervision.

Frontal Sinusitis.—F. P. Calhoun reports a case of traumatic frontal sinusitis operated on by removing most of the external wall of the sinus and thorough curetting. The wound was packed with iodoform gauze and gradually healed in fourteen weeks' time. Two months later a long sinus was discovered discharging mucopurulent matter. At the suggestion of his colleague, Dr. C. R. Andrews, he injected bismuth paste made as follows: Bismuth subnitrate, 30 parts; paraffin (melting point 120), 10 parts; white wax, 10 parts; petrolatum, 50 parts. Two injections, four days apart, sufficed to produce a cure, and more than a year has now elapsed without discharge or other inconvenience. The cavity filled almost completely and the deformity is practically unnoticeable. He reports the case because of the apparent good effects of the bismuth paste in a condition which often resists treatment and is followed very frequently by deformity.

Inoperable Sarcoma.—L. Loeb says of the treatment of inoperable sarcoma by the streptococcus and prodigiosus toxins, that it is a vaccine treatment, and differs from certain other vaccines in not being a specific remedy. These two toxins have no etiologic relation whatever to sarcoma, for the cure of which they are employed. The basis of the method of treatment is in this case an empirical one; it was noticed that an attack of erysipelas in persons afflicted with cancer in a number of cases led to a retrogression of the growth, and even to a cure. Certain acute infectious diseases, however, may also cause a retrogression of cancer. Fehleisen, after his discovery of a streptococcus as the cause of erysipelas, made some inoculation experiments in cancer patients with some beneficial results, and other surgeons likewise reported cures. The living bacteria were employed, however, and sometimes proved dangerous. It was a step in advance, therefore, when Spronck recommended the use of the toxins instead of the living germs, and W. B. Coley only a year afterward began a systematic study of their use in the treatment of sarcoma. Since that time he has persistently continued in this line of work, and has improved it by adding the toxins of *B. prodigiosus* to the streptococcus toxins. Later it was found that the toxins did not have to be derived necessarily from the germs of erysipelas, and it is even likely that toxins of other bacteria may serve the same purpose. The toxins are injected in gradually increasing doses in a part of the body distant from the tumor, and later, if possible, into the tumor itself. Dr. Coley gives the following data of the treatment in sarcoma: "In 430 cases treated the tumor disappeared under the influence of the toxins in approximately 11 per cent. of the cases; 6.5 per cent. of the patients treated have remained without recurrence over three years after the cessation of treatment. In 3 out of

these 430 cases death followed, probably as a direct or indirect result of the treatment. According to Dr. Coley, in 13 cases of sarcoma of long bones, observed partly by himself and partly by other surgeons, the use of the toxins has rendered amputation of the limb unnecessary; in other cases, however, the toxin treatment was without effect. In a series of 22 cases in which the toxins were used after primary operation, 4 patients are now well after periods of from three to eight years, and 9 after periods of from one to three years; in 5 cases recurrence took place in spite of the toxin treatment; the remaining patients are still under treatment or the cases are very recent." Loeb has collected the statistics of the experience of a number of prominent surgeons, and concludes that the treatment of inoperable sarcoma by this method leads to a cure in approximately from 4 to 9 per cent. of cases, and some results obtained suggest that it may be useful as a postoperative procedure in diminishing the number of recurrences, and that in another certain number it might limit the need for amputation of the limb in cases of sarcoma of the long bones. The manner in which it acts cannot be definitely stated, but it is probable that the toxins and their reactions on the local and general syndrome often have an unfavorable effect on the life and growth of the sarcoma cells.

Splint for Fractured Ulna.—Penn-Gaskell Skillern reports a case of fracture of the ulna in the lower third of its shaft in which the inferior fragment was driven outward, encroaching on the interosseous space. Reduction by manipulation was evidently to be maintained by overabduction of the hand. The simplest way to secure this seemed to be to apply a Bond splint in reverse. A right-handed splint was used and the patient was instructed to grasp the semicylindric block with his hand. The shaft of the splint, being free, formed an acute angle with the radial border of the pronated forearm. The hand was secured to the block by adhesive strips applied so as to describe an ellipse between the posterior surface of the bases of the metacarpals and the under surface of the distal end of the splint. The acute angle between the shaft of the splint and the forearm was obliterated by pushing the splint toward the forearm until it paralleled the latter. This forced the hand over toward the radial side in overabduction, and the lower fragment of the ulna was therefore drawn away from the radius as far as the interosseous ligament permitted, and the fragments were perfectly coapted. He quotes from Gross's "Surgery" to show that the principle thus applied is an old one, but thinks it deserves present consideration.

Epidemic Spinal Disease in Nebraska.—G. P. Shidler gives an account of an epidemic of spinal disease recently prevalent in Nebraska which had been diagnosed as cerebrospinal meningitis and acute poliomyelitis, which were neither of them considered quarantinable. When the disease appeared to be highly contagious, however, these diagnoses had to be given up. The epidemic commenced about July 4, and seemed to spread from a Fourth of July celebration in Stromsberg, Neb., with excursions from surrounding towns and counties. Evidences of its contagiousness are given. The author has studied 60 cases, and gives the results. The period of incubation could not be determined in all cases, but in several it was 5 days and in several others from 11 to 13 days, probably depending on susceptibility, resistance, and virulence of the infecting organism. Of the patients, 25 per cent. were under 3 years of age, and 20 per cent. over 10 years. The latest cases occurring in the county are of a higher age throughout. Twenty-nine of the 60 were females and 31 males; 31 per cent. occurred as single cases in families having more than one child, and 44 per cent. in families in which there were two or more children, all of whom took the disease. Most of the patients had been in previous good health. In large families with poor hygiene and sanitation there seemed to be tendency for more cases to occur, but most of the cases were from clean, well-kept homes. Teething seemed to have no effect on acquiring the disease, but overwork seemed to predispose, especially in young men working in the hot sun. The onset was usually sudden, with moderate fever, loss of appetite, and disinclination to play, though in a very few cases restlessness at night and pain on movement were first symptoms noticed. In several of the cases there was no fever, and in only one a chill; 2, 3, and 4-day temperatures seemed to be the rule, falling in 24 hours by crisis. Constipation was the rule. The reflexes were generally sharp and exaggerated during fever. Under subjective symptoms, a basilar headache was most important and constant, often with pain in the back of the neck and general hyperesthesia of back and limbs. In the more severe cases perfect rigidity of the neck muscles was noticeable. The worst paralysis occurred in children from 8 to 12 years of age when the disease was not fatal. In 10 cases there was no paralysis, and 11 only incoordination. Paralysis of both legs was the most common form. Recovery was generally good in mild cases, but in the severe cases which were not fatal there was usually a slight improvement, followed by atrophy of certain groups of muscles, most frequently the deltoids, pectorals, quadratus femoris, and tibialis anticus muscles. The mortality was 11 per cent. in the 60 cases. The ratio was highest in the later occurring ones. As to the nature of the disorder, Shidler says there is nothing in the symptoms that could not occur in a simple meningitis caused by some unknown organism. In 9 cases out of the 60 and out of 14 in which lumbar puncture was performed, what appeared to be a Gram-positive coccus was obtained and in three a diplococcus, but never intracellular. The spinal fluid was clear as water in every case but one in which it was slightly turbid and showed the only polymorphonuclear leucocytosis. The clear spinal fluid, comparative rarity of cerebral symptoms, and relatively low death rate almost completely exclude in his opinion the diagnosis of cerebrospinal meningitis and therefore the possibility of good results from Flexner's serum. The chance of its occurring in connection with another disease, however, must not be overlooked. The mortality is too high for the poliomyelitis of the text-books but he asks if the simple meningitis and the poliomyelitis may not have a common cause, the symptoms of one sometimes predominating and sometimes those of the other. He asks: "Is it not natural to suppose that in most cases, on account of the blood supply and the proximity of the membranes to the cord substance, the two infections go hand in hand and that, while poliomyelitis may leave the predominating lesion usually, at any time it would be possible for the meningeal symptoms to appear uppermost?"

Lancet, January 15, 1910.

Septic Infection Consequent on Mastitis.—The patient of A. D. Pithie was a married woman who was delivered of an eight months child in June and made a fair recovery. The left breast ached from the time of confinement. An inflammatory lump formed in it and it was fomented. The symptoms ran on and early in October the lump suppurated and discharged. Then she had a rigor with sickness and faintness. When the author saw her early in October she was in great distress and manifestly septic. No pus pocket could be found. There was an intensely red rash upon the chest and neck. Quinine and strychnine were given but without avail. Then antistreptococcic serum was injected into the walls of the abdomen but the patient vomited. It was next given by rectum, and although the patient at first retched after each administration, tolerance was established. Finally she made a slow but perfect recovery. The points of interest in the case are the evident absorption of septic material from a mastitis without any evident collection of pus; the prompt and satisfactory action of the serum after quinine had been given without good effect; the recurrence of the symptoms a few days after the serum had been stopped, and the controlling effect of the serum when again resorted to. This leads the author to think that in similar cases it would be well to continue the administration of the serum for some time after all symptoms had subsided if even in smaller and less frequent doses.

Displacement of the Semilunar Cartilages.—K. H. Digby gives a general description of these structures and illustrates his paper with several diagrams. Regarding the causes of this injury he makes the following observations, basing his views on 100 consecutive cases operated on at Guy's Hospital. A slip or twist while running, walking, or dancing may cause it. The wrench at the knee, especially in recurrent cases, may be trivial. Catching of the inner side of the forepart of the foot against some obstruction or catching the foot in a hole or between two planks may act similarly; turning suddenly on one leg, sudden or short falls on one leg, being tripped up, attempting to rise after squatting some time upon the toes, turning over in bed, one foot being caught by the bed clothes, climbing a ladder or going up stairs, kicking at a football with the inside of the forepart of the foot, catching the foot in some moving structure, the result of direct violence, all these conditions have been the cause of the accidents which have come under his personal observation. Conservative treatment may sometimes result in benefit. The cartilage if displaced is reduced by manipulation. If all rotary movements are restrained adhesions will form. Apparatus should be worn which admits of flexion and

extension but prevents rotation. The usual lesion in all these cases is excessive outward rotation of the tibia beneath the interarticular cartilages producing a laceration of the capsular attachments of the forepart of the internal semilunar cartilages. The ligamentum patellæ is often relaxed and thus the tension on the lacerated capsule is relaxed. The relaxed condition may result from repeated effusions into the joint. Strong outward rotation of the tibia gives rise to pain over the peripheral attachment of the internal semilunar cartilage. Strong inward rotation is painless.

Fatal Phosphorus Poisoning with Unusual Subcutaneous Hemorrhages.—R. G. Hann and R. A. Veale report the case of a girl, unmarried, who, on account of pregnancy, took a dram of rat poison containing about 4 per cent. of phosphorus. She vomited, but continued about until the third day, when one foot began to swell and she began to vomit blood. A profuse uterine hemorrhage appeared. She had severe abdominal burning pain unrelieved by large quantities of water. She came under observation on the fourth day. Below the waist line more than half the skin area was the seat of enormous subcutaneous hemorrhages. The remaining skin was normal. There was no jaundice. She died that same night. Autopsy showed blood-stained serum in the pleural cavities, much hemorrhage in the mediastinal tissues, extensive retroperitoneal hemorrhages especially about the left kidney, and also in the omentum and mesentery. The heart and lungs were normal. The liver was enlarged and of a bright canary yellow color. There were hemorrhages into the wall of the gall-bladder. The kidneys were of normal size but of a pale yellow color. The stomach mucosa appeared normal, but the organ was full of dark colored fluid. Marked fatty degeneration was present. The author says that in at least 80 per cent. of these cases jaundice is present. As is usual, the primary symptoms of gastrointestinal irritation were marked off from the secondary symptoms of toxic poisoning due to hepatic failure, by a period of comparative comfort on the beginning of the third day, but the thirst was intense throughout. Such extensive subcutaneous hemorrhages as this case presents were unlike those seen in any case of purpura and, as far as he knows, have never been recorded in any previous case of phosphorus poisoning.

Infective Endocarditis as a Complication of Pregnancy.—Two cases are reported by E. E. Norton. Both resulted fatally. In the second case the fatal issue was doubtless hastened by uremic conditions following on widespread changes in the kidney. Both followed on miscarriage in single women and the endocarditis was presumably due to infection and death of the fetus *in utero*. Death had probably no relation whatever to any attempts which had been made to terminate the pregnancies. The cases were of the fulminating type, though in one case there was some cardiac hypertrophy. In one case the cardiac condition was not diagnosed. In the second case it was suspected on account of the petechial eruption. Infective endocarditis is apparently of extreme rarity as a complication of pregnancy. One author did not find pregnancy in 150 cases of infective endocarditis collected by him. Each of the two cases reported occurred in young unmarried women on whom attempts at abortion had been made. In each there followed a sudden attack of severe illness, miscarriage occurred, and death followed rapidly upon a profound toxemia. The symptoms bore the strongest resemblance to those which might have been produced by septic complications following upon abortion criminally produced by the use of instruments. The heart in one case showed on both mitral cusps an irregular row of rough vegetations. There was no peritonitis. In the other there was a large mass of rough vegetation on one mitral cusp and also on each aortic cusp there was a row of warty vegetations of considerable size to one of which a large clot adhered. Peritonitis was also here wanting. In neither were there any signs in the uterus of instrumental interference. Several similar cases are referred to by the author.

The British Medical Journal, January 15, 1910.

Some Points in the Treatment of Nerve Injuries.—J. Sherren calls attention to the importance of the following points: (1) Fine catgut should be used to unite the ends of the nerves, plain if there is no tension, lightly chromicized in cases in which any tension falls on the junction. Nonabsorbable material, silk, linen, thread, or celluloid thread, should be avoided. They give rise to symptoms in many cases months after their employment when recovery is well advanced, causing relapse and seriously interfering with complete recovery. (2) In all cases in which a nerve has been wounded it should be protected from forming adhesions to surrounding structures by wrapping in Cargile membrane. When tendons have been divided they should be treated in a similar way. Failure to protect the nerve is responsible for imperfect recovery in a certain number of cases and often necessitates a second operation even when the nerve was not completely divided. (3) After wounds in the region of the wrist the deep fascia should always be carefully sutured. If this is not done the tendons may become adherent to the skin, interfering considerably with their mobility and in many cases when the wound has been extensive a hernia of tendon forms which is a source of weakness until remedied by operation. Operation is, however, only the first step toward recovery. Paralyzed muscles must be kept in good tone and for a while relaxed by proper apparatus. Failure to attend to these points is responsible for many incomplete recoveries. It is rare to have nerve involvement after major amputations, for it is now a recognized step in these operations to pull down and cut short the nerve trunks. This is often neglected in amputations of the fingers, but it is a matter of the greatest importance.

On the Orifices of the Body.—P. Daniel discusses this subject with special reference to the latency of disease and overlooked infections. He says that in many cases of illness no satisfactory or sufficient cause is found or that some simple explanation is forthcoming and that in the vast majority of cases this is an infection of some one or more of the cavities of the body. Invariably some one of the mucous surfaces is at fault. The most important ones are the mouth and nose, urethra and vulva. The bacteria chiefly concerned are the cocci, and they may be broadly specific, setting up directly septic processes, may break down the resistance of the body so that other pathogenic bacteria are enabled to invade successfully the other structures or they may co-operate with and increase the destruction and toxemia due to other bacteria. An enormous number of the diseases which make themselves manifest in adolescence begin in infancy. Some of the graver diseases are congenital. Repeated small infections and intoxications ultimately give rise to violent disorders often culminating in violent septicopyemia. A large number of symptoms are set up in various parts of the body which are considered separate disease entities, but are really merely secondary to the frequent and long-continued infections. Orificial disease is universal among the poorer classes and exceedingly frequent in the higher classes if we look for it properly. Oral sepsis is an actual potent factor in the causation of every day disease. The author found only 10 cases in 5,000 patients who had absolutely healthy mouths at the time of examination. Many patients daily swallow pus in quantities varying from a few minims to half an ounce. Such a continual infection is responsible, according to the author, for such maladies as goiter, neuritis, arthritis, so-called heart disease, general ill health, and hysteria. Many cases of hepatic cirrhosis, erroneously ascribed to alcohol, are really due to sepsis. So also may be such diseases as insanity, uremia, Charcot's joint lesions, tabetic crises, laryngismus stridulus, etc. In all these lesions some orifice of the body is very frequently at fault. Particularly does the genitourinary tract furnish evidence of this. The author says that from the standpoint of prognosis in other diseases and from the post-operative standpoint the presence or absence of an infected genitourinary or a gastrointestinal orifice is of incalculable importance and yet he constantly sees patients suffering from phthisis or chronic pulmonary lesions in whom there are septic tonsils, stumps, purulent gingivitis, submaxillary calculi, otitis media, etc., which have been entirely overlooked and ignored in the battle against the tubercle bacilli. The main teaching of the author's suggestive paper is to make a thorough examination of all the orificial cavities of the body in our search for the ultimate cause of disease.

Causation of Angina Pectoris.—Byron Bramwell notes that in the great majority of cases of angina pectoris, the pain radiates down the left arm, sometimes down both arms, and very rarely down the right alone. He believes that in most cases the sequence of events is as follows: First. A sudden strain is thrown on the left ventricle due to exercise or a sudden increase of the peripheral resistance. It may be merely relative to the weakened ventricle. In some instances in which the cardiac nerves or muscles are diseased the attack arises independently of any sudden exertion. Under such conditions a strain on the ventricle which under ordinary circumstances would not be attended with cardiac pain would be sufficient to produce the condition. Second. In consequence of this strain those of the left ventricle fibers which are degenerated either as a re-

sult of deficient blood supply or of degenerative changes in the cardiac muscle irritation of the cardiac sensory nerves is produced. The exact cause of the irritation of these nerves is not clear and this seems to the author to be the point in angina pectoris which needs to be cleared up. It may be spasmodic contraction of some of the fibers or perhaps increased tension in the cavity of the ventricle. Third. Irritation of the cardiac sensory (afferent) nerves in the wall of the left ventricle is reflected by the sympathetic branches of the cardiac plexus distributed to the left ventricle and the spinal cord in the form of pain to the periphery. This explanation is in accord with the following clinical facts: First. That the exciting causes of angina are increased muscular action and conditions which produce increased pressure in the peripheral arterial circulation, second, that in many cases the paroxysm is at once relieved by rest and by remedies which rapidly reduce arterial tension and so take off the strain from the left ventricle and, third, that in some cases of angina pectoris the attacks of angina disappear with the development of mitral regurgitation. In addition the author believes that in those instances in which both arms or the right alone is affected the cause of the pain whatever the exact lesion may be is referable to involvment of the root of the aorta or of the aortic arch. Another explanation of the pain in the right arm is to suppose that the nerve terminations in the wall of the right ventricle have become irritated. The most constant pathological change found in fatal cases is atheroma of the coronary arteries. As a result of muscular effort the blood supply may be suddenly diminished and the attack consequently occurs. We have alluded only to some of the interesting points brought out in this able paper.

Berliner klinische Wochenschrift, January 3, 1910.

The Physiological Loss of Weight in the New Born.—Hirsch has made a careful study of the loss of weight in a series of infants during the first few days of life, and has compared these figures with the weight of the meconium passed during the same period. From these researches he concludes that the so-called loss of weight of the new-born is only apparent, and is almost entirely accounted for by the amount of meconium passed. The primary weight expresses the weight of the child plus the meconium; the minimum weight represents the net weight of the infant. There is but a very slight actual loss of weight, namely, from 10 to 20 grams, during the first few days, due to destruction of albumen and loss of water through the skin. With proper nourishment the birth weight should be regained on the eighth day.

Münchener medizinische Wochenschrift, December 21, 1909, and January 4, 1910.

Artificial Formation of a Vagina by Means of a Loop of Intestine.—Mueller reports the case of a young unmarried woman, aged 21, who came under treatment for amenorrhea. The breasts and external genitalia were found to be quite normal and well developed. The urethral orifice was much enlarged and in the form of a slit. Between this and the frenulum, in the place of a vagina, was a flat scarlike patch the size of a 25-cent piece. Examination with the little finger in the bladder and the index finger in the rectum failed to demonstrate a trace of any organ between the rectum and bladder. The patient had never menstruated. Considering the difficulty in obtaining satisfactory results with the usual plastic operations on the vagina, the author attempted the procedure recommended by Mori in 1907, of implanting in the site of the vagina a loop of small intestine. Under chloroform and ether anesthesia, an incision 4 cm. long was made in the middle line between the urethra and frenulum. The rectum and urethra were carefully separated. The ease of this suggested that one was working in a preformed split. After provisional packing of the wound, which was one finger length deep and admitted two fingers, laparotomy was performed. The pelvis was found to contain only the rectum and the bladder. On the right side, at the level of the pelvic inlet, on the innominate line, appeared a small, red body the size of a small hazel-nut, which was recognized as a rudimentary uterus. From the right cornu of this was a thin, round ligament. The ovaries were found to be two string-like bodies, 6 to 8 cm. in length, and the size of a lead pencil. The left contained a fresh corpus luteum. A loop of small intestine, 30 cm. from the cecum, was now taken, and a portion of this, 14 cm. long, resected. The gut was then united by end-to-end anastomosis. The resected loop was kept in gauze. After the anastomosis the upper end of the resected loop was closed with three layers of stitches. The gauze was removed from the perineal wound, and a forceps inserted and forced through the peritoneum, the opening being widened with the clamp. The piece of intestine was inserted through the wound so that the mesentery border lay anteriorly. The lower end of the gut was stretched to the vulvar wound. The upper end showed behind the bladder. The abdomen was closed, and the new vagina packed with gauze. Recovery was uneventful, and six months later the new-formed "vagina" was smooth and easily patent for an examining finger. The author discusses the moral aspect of the justification of the operation.

Positive Wassermann Reaction in Acute Lupus Erythematosus.—Hauck says that after an examination of 15,000 cases by the Wassermann reaction it may be said that it is to a high degree specific for syphilis. Positive reactions have, however, also been obtained in yaws, trypanosomiasis, leprosy, scarlet fever, and malaria. Recently Reinhart reported a case of acute lupus erythematosus with no history of syphilis which gave a positive reaction. The author reports a similar case in which on two occasions during the disease marked positive hemolytic tests were given. The patient was treated with quinine and recovered from the disease. After recovery the Wassermann reaction was negative. In a case of chronic lupus erythematosus the reaction was negative.

The Quinine Treatment of Pemphigus.—Bergrath says that previously no satisfactory method of treating pemphigus has been known. Spiegler says that nothing should be done; Hutchison advised arsenic; Neisser, strychnine; and Mosler, quinine and atropine. The present author has used large doses of quinine in two cases of severe pemphigus. In the first case, a girl of 21, with pemphigus beginning on the conjunctiva and covering the entire body, an improvement appeared three days after the beginning of the treatment with quinine. The quinine was begun in doses of 7 grains three times a day. At the end of two weeks the general improvement was so great that the patient was allowed to get up and go out in the garden. The dose was then increased to four times a day, without symptoms of quinine intoxication. In six weeks she was discharged cured. The second case was a woman of 48, also suffering from typical pemphigus vagitans. After she had steadily grown worse under arsenic and strychnine treatment, quinine was begun, with 4 grains four times a day. This was increased to 30 grains daily. Whereas during the first three days of this treatment new bullæ appeared, after that they ceased entirely. The patient gained weight. The eruption disappeared. The signs of gastrointestinal involvement cleared up so that the patient again ate solid food, and she was sent home after 2½ months quite well, except for scars of the old bullæ. Though the author does not care to pronounce the cases as permanently cured after this brief period of observation, he says that the improvement was so striking that quinine should be tried in every case of pemphigus. It is not impossible that by a prolonged intermittent quinine cure, finally the pemphigus process may be completely stamped out.

Runner's Cramp.—Schmidt reports the case of a young athlete who had run from one to one and a half miles daily for four years. Two weeks before admission to the hospital he had severe cramps in his calves. This disappeared when resting, but recurred as soon as he tried to run. There was marked hyperextension of all toes. Rest in bed relieved symptoms in two days, but every attempt to run brought them on again.—*U. S. Naval Medical Bulletin.*

The Toxic Power of Blood Serum.—A. Gasbarrini gives the results of his experiments by the injection of blood serum of various animals into the rabbit. Large amounts of the serum were injected endovenously and subcutaneously, serum of the ass and ox being used. The serum was sterilized and kept at a temperature equal to that of the animal receiving the injection. The serum of the ox has a poisonous effect on the rabbit, causing death in a few minutes with generalized flaccid paralysis. The temperature of 55° destroyed the toxicity of the serum, which could then be injected with impunity into the rabbit. The resistance of the animal could be increased by injections of small doses of fresh serum, by immunizing the animal by doses of serum heated to 55°, or by injecting into the venous system, a few minutes previously, a certain dose of boiled serum. Fresh serum of rabbits immunized by serum of asses or oxen heated to 55°, and used in small amounts had a protective action against otherwise mortal doses of serum of the ox.—*La Riforma Medica.*

Book Reviews.

Leitbuch der specifischen Diagnostik und Therapie der Tuberculose. Für Arzte und Studierende. Von Dr. Bandelier und Dr. Roepke. Dritte Erweiterte und Verbesserte Auflage. Mit einem Vorwort von Wirk. Geh. Rat. Prof. Dr. R. Koch, Exzellenz. Mit 19 Temperaturkurven auf 5 lithographischen Tafeln, 1 Farb. lith. Tafel, und 4 Testabbildungen. Würzburg: Curt Kabitzsch (A. Stuber's Verlag), 1909

The third edition of this treatise on the specific diagnosis and treatment of tuberculosis quickly follows the second issue. The present edition contains some introductory words from Robert Koch. Otherwise it is little changed from the previous editions, except that the latest judgments of the value of the cutaneous and conjunctival tuberculin tests are considered. The book contains everything necessary for understanding and carrying out the principles of diagnosing and treating tuberculosis with the specific remedy tuberculin. It is the most complete volume dealing with the subject that we have seen.

Klinische und Experimentelle Studien zur Pathologie und Therapie der Tuberculose im Kindesalter. Von Dr. Bauer und Dr. Engel. Mit 11 tafeln und 4 Abbildungen im text. Würzburg: Curt Kabitzsch (A. Stuber's Verlag), 1909.

This pamphlet consists of two exhaustive studies of tuberculosis of children that have appeared in the "Beiträge zur Klinik der Tuberculose" during the present year. Dr. Engel's study concerns itself with the reaction of the child's organism to tuberculin. Dr. Bauer writes of the phenomena of immunity in tuberculosis. Both articles present a great number of facts derived from the observation of actual cases of the disease. While appealing especially to the scientific students of tuberculosis, they may be read with profit by the general practitioner and by the pediatrist.

The Malarial Fevers, Hemoglobinuric Fever, and the Blood Protozoa of Man. By Charles F. Craig, M.D.; Captain, Medical Corps, U. S. Army; late Pathologist and Bacteriologist to the Sternberg U. S. Army General Hospital, Chickamauga Park, Ga.; the Josiah Simpson General Hospital, Fortress Monroe, Va.; the Camp Columbia Hospital, Havana, Cuba; the U. S. Army General Hospital, Presidio of San Francisco, Cal.; the Division Hospital, Manila, P. I., etc. Illustrated by four colored plates, twenty-five clinical charts, and 28 photomicrographs and drawings. New York: William Wood & Company, 1909.

While the number of supposably exhaustive monographs on the subject of malaria is very considerable, none of the volumes that has as yet appeared can compare at all either in authoritativeness or completeness with the present work. Captain Craig is universally recognized as one of the world's foremost students of the malarial infections, and the many years he has devoted to their investigation under conditions unusually favorable for research give a weight to his views that almost forces their acceptance, even when they are at variance with those of some of the other observers in this field. It is therefore of great interest to note with what decision he takes a stand in regard to certain mooted points, and undoubtedly the expression of his convictions will do much to modify the general opinion concerning them. For example, he is very emphatic in asserting that two distinct types of estivoautumnal parasites occur, *Plasmodium falciparum* and *Plasmodium falciparum quotidianum*, giving rise to infections clinically distinguishable by their temperature curves, unless the picture has been obscured by the administration of quinine. He is equally positive in removing black-water fever entirely from the category of the malarial infections, and presents evidence clearly demonstrating that the disease must be due to some cause other than the malarial plasmodium, and also that quinine is not the etiological factor, as has often been alleged. It is a pleasure to read the chapter on coincident typhoid and malarial infections, in which the author urges the abandonment of the term "typhomalarial fever," that convenient diagnostic ragbag so often resorted to as an excuse for careless or insufficient observation, not infrequently to the great detriment of the patient. While coincident typhoid and malarial infections do sometimes occur, this is very rarely the case, and their number is insignificant. Craig goes so far as to state there is good reason for believing that there is even a certain amount of incompatability between the two infections, "for it is frequently observed that when typhoid develops in a patient suffering from malarial fever, the malarial symptoms disappear, as well as the plasmodia from the peripheral blood, and only reappear during convalescence from the typhoid." Naturally he lays the greatest possible stress on the importance of the examination of blood preparations, preferably stained and by Wright's method, in all cases in which there is a possibility of the existence of malaria, and doubts the statement sometimes made that cases of malarial fever may occur in which it is impossible to demonstrate the parasite. Space forbids the detailed discussion of the book that its importance deserves, every page bears the impress of careful, thoughtful, original work, and it should certainly be studied by every practitioner of medicine. The addition of the chapters on the other blood protozoa usefully complete the volume, and though the filarial infections do not, of course, strictly speaking, fall under this head it might be suggested that a brief discussion of their manifestations in the blood could advantageously be included in a future edition. The book is beautifully printed and illustrated, and will without doubt prove to be one of the most important publications of the year.

Diathesis and Ocular Diseases. By A. Maitland Ramsay, M.D.; Fellow of Faculty of Physicians and Surgeons, Glasgow; Ophthalmic Surgeon, Glasgow Royal Infirmary; Lecturer on Eye Diseases, Queen Margaret College, University of Glasgow; Author of "Atlas of External Diseases of the Eye," "Eye Injuries and Their Treatment," etc. New York: William Wood & Company, 1909.

This book is one of 184 pages, with 27 illustrations in the text and on plates. The volume contains the postgraduate lectures delivered at the Glasgow Ophthalmic Institution in September, 1908. Chapter I is introductory. Diathesis is defined as "a bodily condition predisposing to a particular disease." Then follow chapters on "The Neurotic Diathesis," "The Scrofulous Diathesis," and "The Arthritic Diathesis." The relation of these diatheses to diseases of the eye is considered in various chapters in logical sequence, and the treatment of the affections described is quite fully entered into. The general condition of the body and its influence on the eye is a subject of no mean proportions, meriting careful study. The author of this work has presented the matter in an attractive manner, and has produced a volume that is well worth the attention of ophthalmologists.

Blindheit und Blindenwesen. Von Augenarzt Dr. med. Hübner, in Cassel. Halle a. S.: Carl Marhold Verlagsbuchhandlung, 1909.

This monograph is devoted to a consideration of what constitutes blindness in an absolute and economic sense, an inquiry into the causes of blindness, a consideration of the measures best adapted for prophylaxis, and, finally, the measures employed in improving the mental condition of the blind by the various means of education, principally through the senses of touch and hearing. The author has devoted much time to the study of the subject, and has presented it in a most interesting and instructive manner.

Clinical Manual for the Study of Diseases of the Throat. By James Walker Downie, M.B., F.R.C.S., Lecturer on Diseases of the Throat and Nose, University of Glasgow, etc. Second Edition, revised and in large measure rewritten. Glasgow: James Maclehose & Sons; New York: The Macmillan Co., 1909.

This is a second edition in name only, for its predecessor has been remodeled, nearly wholly rewritten, and brought up-to-date. The subject matter has been subdivided under a sufficient number of suitable headings in order to facilitate references, while several new and original illustrations and some new colored plates have been added. Short notes of several interesting cases are given. The author is well known as an accurate clinician, and is a teacher of experience. His style is simple, and he has crowded much information into his pages. His work bears throughout the impress of practicability.

Dose-Book and Manual of Prescription-Writing. With a List of the Official Drugs and Preparations, and Many of the Newer Remedies, with Their Doses. By E. Q. Thornton, M.D., Ph.G., Assistant Professor of Materia Medica, Jefferson Medical College of Philadelphia. Fourth edition, revised and enlarged, and adapted to the eighth revision (1905) of the United States Pharmacopœia. Philadelphia and London: W. B. Saunders Company, 1909.

In the present revision the author has enlarged the sections dealing with solvents and incompatibilities, and has rewritten the table of solubilities. The volume should prove useful to beginners in prescription writing, as it contains in clear and concise form the essentials of that subject, together with the composition, strength, and dosage of all official preparations. But it is a pity that in a fourth edition so many errors in Latin should be allowed to remain to disfigure an otherwise valuable book.

Society Reports

MEDICAL SOCIETY OF THE STATE OF NEW YORK.

104th Annual Meeting, Held at Albany, January 24, 25, and 26, 1910.

THE PRESIDENT, DR. CHARLES G. STOCKTON OF BUFFALO, IN THE CHAIR.

(Special Report to the MEDICAL RECORD.)

(*Concluded from page 211.*)

Wednesday, January 26—Third Day.

The Relationship Between the State Board of Regents and Training Schools.—Dr. JOSEPH MERZBACH of Brooklyn gave a brief history of training schools for nurses, their former requirements and the present requirement for entrance. He outlined the present-day course of instruction. The number of training schools for nurses in this country was about 1,500; the necessity for such a large number was brought about by reason of the increased number of hospitals. He offered suggestions for improving the present methods of instructing, examining, and registering nurses.

Some Unsolved Problems in Relation to Nurses' Training Schools.—Dr. CHARLES STOVER of Amsterdam told of the evolution of the nurses' training schools, the control of the State Board of Regents and its deference to the New York State Nurses' Association. There were 500 pupils in attendance at schools in this State, and the expense of their education was enormous. Dr. Stover called attention to the indifference to this subject by medical and hospital authorities and the public that financed the schools, but which got in return but one-tenth of its nursing. He planned for some future expression of medical opinion.

Mr. DOWNING of the State Educational Department said he had studied the question of nurse training for over a year since he had assumed official duties in the State Educational Department, and the problems that were involved. He said he was in sympathy with the frame of mind of those who had spoken, and he thought the time was ripe when there should have been provision made by statute for a class of nurses to be known as domestic or practical nurses. An attempt should be made to give the poorer classes a body of attendants competent to perform the ordinary duties required in the care of these patients and at a price the people in ordinary circumstances could afford to pay.

Test Meal and Feces Examinations; Some New Methods and Their Clinical Value.—Dr. ANTHONY BASSLER of New York said that test meal analyses of the usual kinds gave negative findings in the great majority of cases of gastric cancer and latent ulcer, and the usual dietetic tests observed from feces examinations often lead one astray, and that in states of chronic intestinal putrefactions the examinations of the feces were most difficult laboratory matters. Therefore, he believed that any additional tests by means of which the scope of diagnosis of gastrointestinal affections were increased were worthy of consideration. His methods consisted of the examination of test meals and feces by means of the bacteria contained in them. A special form of fermentation tube was shown in which the resulting gases were observed in per cents., the bacteriological examinations made, indol and uroresine observed, the various gases analyzed, and the reactions noted. From the normal stomach a test meal in which the hydrochloric acid had been neutralized in advance showed practically no gas result, and the same was true of the primary and secondary neurotic and nutritional conditions of the organ. In latent ulcer and beginning cancer (because of the ulceration present) the bacterial content was higher than normal and gas result might be seen. The same was true of those conditions in which the hydrochloric acid in the stomach was chronically low. In benign stenosis of the pyloris sulphurated hydrogen in the test meal might be most valuable for differential diagnosis.

In his opinion, conditions of digestion in the intestines were more responsible for stomach distress than were the primary stomach conditions. Krehl and Cohnheim had shown that in dogs, injections into the intestines influenced gastric functions most markedly and clinical work strongly suggested that this was also true in the human being. He believed that indicanuric conditions could cause either a depression or aggravation of the stomach secretions in different persons. The main anaërobes in chronic putrefactive conditions of the intestines were *B. coli communis, B. aerogenes capsulatus* and the Gram positive diplococci, and all of these were easily cultivated by his methods and were readily distinguished in the examinations. In regard to the saccharo-butyric and the combined types of chronic intestinal putrefaction of high degrees he drew attention to the various stomach conditions of sensation, secretion, and motility that accompanied these cases. In them a starch and fat intolerance might exist from which there resulted a subnutrition and lack of resistance against acute infectious diseases, particularly of the catarrhal forms that attacked the upper respiratory tract. The indolic type was responsible for many of the intractable cases of neurasthenia, physical and mental debility, headaches, gastric and intestinal atony, prolapse of the abdominal viscera, chronic anemia, and more or less steady and progressive invalidism.

The Importance of Care in Closing the Abdominal Wound.—Dr. LEROY BROUN of New York read this paper. He said it was of interest to note the wide range of difference in technique in closing abdominal wounds; the majority of men, however, were in the habit of using some form of layer suture. Many reinforced the sutured layers by a few nonabsorbable through and through sutures extending either through all of the layers, including the peritoneum, or down to the peritoneum but not including it. His interest in this subject was aroused by an occurrence in his private practice. An abdominal section was made and the wound was closed by bringing the edges of the peritoneum together with a continuous suture of No. 1 catgut. Two or three safety sutures of silkworm gut, including the skin and fascia, were introduced and tied after the skin was closed. The skin was coapted with a continuous suture of black silk. On the morning of the twelfth day after the operation, the wound appeared to be in excellent condition. That evening he was summoned with the statement that the patient was in collapse after a fit of coughing. On lifting the dressings, loops of small intestines were seen protruding from the separated wound. The wound had opened for its entire length. Inspection of the edges did not show any necrosis. The layers could not be clearly differentiated, and the location of the fascia was, however, plainly marked by broken loops of chromic gut. This occurrence, while the first of its kind in his individual work, was by no means confined to a few cases. Madelung collected 137 cases of rupture of the abdominal wound with escape of intestines. Ries reported three cases of his own. The explanation of the rupture of the wound was simple, namely, the pressure from within suddenly applied as resulting from sneezing, coughing, vomiting, or straining at stool; and secondly, a defective or too quickly absorbed suture. Under an exciting cause rupture took place in the large majority of the reported cases at the time when the sutures had lost their supporting powers by being dissolved or otherwise, or having been removed if of nonabsorbable character. In general the complete separation of the wound

must commence first, by the separation in part of the deeper layers, as a result either of the snapping of the retaining sutures as advanced by Ries, or by their absorption, or cutting through, or a possible untying of the knots. The separation once commenced was completed by the pushing up of the intestines. At a later time, as advanced by Ries, whether within a few hours or days, the skin union separated permitting the escape of the coils of intestines. This was generally coincident with the removal of the skin sutures. In suturing the abdominal wound Dr. Broun's custom was to bring the peritoneum together with a running suture of No. 1 plain gut. The muscle was coapted with a few sutures of interrupted No. 2 plain gut. He closed the fascia with No. 2 or 3 chromic gut interrupted about every one and a quarter inches. The skin was brought together with a running suture of silk. Under certain circumstances lapping the fascia added to the security of the wound. A firm supporting dressing was then applied. The adhesive strips were not removed for two weeks after the operation, but were tightly laced after each subsequent dressing.

Dr. Whitbeck of Rochester said it was very important that the safety sutures should not be drawn too tight.

Dr. Walter B. Chase of Brooklyn said that when the incision was not in the median line of the abdomen, cases in which hernia was more likely to occur than when a median incision was made, added security was given by overlapping the layers, and especially the transversalis fascia.

The Chauffeur's Fracture.—Dr. William S. Thomas of New York described the mode of production of this fracture, a subvariety of a Colles' fracture. A detachment of the styloid process of the ulna was noted in seven of his skigrams. Severe silver-forked deformity was not found. The mechanism of the injury seemed to be one of avulsion. The chauffeur's fracture was a badge of carelessness. Immobilization of the wrist and rest was all that was required in the majority of the cases. The patient usually was able to return to work within three weeks.

Shall All Fibroid Tumors of the Uterus Be Removed with the Knife?—Dr. Frank DeWitt Reese of Cortland read this paper, which was based upon his experience with eighty-two cases that occurred in his private practice. Uterine fibroids were found at all ages. He was convinced that the malignant troubles associated with so-called fibroids were really adenomyomata or some other mixed tumor. The causes were not known. Among the eighty-two cases, seventy-seven suffered from pain at the first menstrual period. Fibroids of the uterus were of slow growth. Large sized fibroids with a small pedicle should be removed. When there was much bleeding, curetting should first be done; if bleeding continued, and if the hemoglobin percentage was not too low, operation was called for. Intramural fibroids pure and simple were amenable to nonoperable treatment. The success of the nonknife treatment depended upon an early diagnosis, and the persistence in carrying out the constitutional treatment.

The balance of the morning was devoted to a symposium on vaccine.

A Case of Human Glanders Treated by an Autogenous Vaccine, with Recovery.—Dr. A. T. Bristow and Dr. Benjamin White of Brooklyn made this report. From 1905 to 1909 only seventeen deaths of human glanders were reported to the Board of Health. More cases had not been reported probably because they had not been recognized. An account of a case of atypical human glanders was given; the case could not have been recognized except by laboratory methods. An autogenous vaccine, made from the patient's own organisms, was given, with recovery. A summary of the treatment was given. Fifteen injections were given. They began with ten million dead bacilli and ended with three hundred million. The source of the infection could not be traced. The importance of an early diagnosis could not be overestimated.

The Treatment of Surgical Tuberculosis by Vaccines.—Dr. James A. McLeod of Buffalo said that in the scope of the paper it was an almost insurmountable difficulty to attempt to correlate and condense the facts that were necessary for a free discussion of the subject. Since Koch first announced his discovery, investigators from all quarters had poured into the literature the fruits of their investigations. This vast amount of work, resulting in no definite goal, had had its origin in the fact that the tubercle bacillus had not conformed to the lines followed by the great mass of bacteria. Such being the case he asked that it be granted, (1) that up to the present they had no exact knowledge of the true toxins elaborated by the bacillus; (2) that they had no conception whatever of the immunity response by the body to combat an invasion by the organism; (3) that they were not even certain whether the body enjoyed a general, or but a local resistance toward the bacillus. Tuberculosis was essentially a local disease; but was the resistance offered to it by the body a general one, that was, one lying in the blood itself, or a local one, that was, one lying in the tissues themselves, or was it a combination of the two? The probability was that it was a combination of the two; otherwise contradictions existed. The tubercle bacilli themselves, and by this he referred to the human and bovine types chiefly, were in their present knowledge among the most highly organized in the bacterial world. It would seem, according to some authorities, that these two types were the result of an evolution, which had raised them from the ranks of the lowest nonpathogenic forms of acid-resistant bacteria, such as were found everywhere in nature, through hosts of increasing complexity, until the present parasitic stage had been attained. Infections with the tubercle bacillus were local ones and except in certain conditions they did not *per se* produce temperature; yet from the local foci, toxins must be absorbed; otherwise no harmful effects would ensue. What the toxin was, they did not know, nor had it ever been obtained. Marmorek's serum was said to contain this toxin, but this had not been proved. Tuberculin, it was said, did not contain it, and yet it had a known curative value. Since Koch's first announcement of his discovery of the tubercle bacillus, every conceivable method had been exploited in attempting to produce either an active or passive state of immunity or resistance towards the bacillus. Von Behring declared that in his bovovaccine he had discovered jennerization, as applied in his experiments, to the raising of an immune state in calves, toward the bovine forms of the disease. Unhappily, recent announcements showed clearly that no immune state existed; it was only a resistance, lasting over a variable short period of time, to be followed by a state of increased susceptibility. That no immune state existed was proven by the recovery of living virulent bacilli from the lymph glands of the animal inoculated. Jennerization had failed, pasteurization had failed, the various sera had failed. Tuberculin alone had given a certain measure of success. What the action, or reactions, of the various tuberculins was, they did not know for certain, but it was believed that the action was upon the tuberculous disease, and not upon the bacilli themselves. Wassermann had proved that antituberculin was present in the tissues, but it had not been proved that this substance was bactericidal. Nor had the agglutinins been shown to inhibit the disease. It was so with all other bodies with the one possible exception, the opsonins. Wright and Douglas claimed that these opsonins were bactericidal, and demonstrated that by increasing their content in the serum, the phagocytic power of that serum was raised. They deduced from this that opsonins were distinctly responsible for immunity to certain diseases. Although such a rôle could not be placed entirely to the credit of these bodies,

yet certainly the fact remained that, subsequent to inoculation with tuberculin, the opsonic content of the blood was increased. With this increase clinical improvement became manifest. Whether this improvement was due to the opsonins, or simply to a local hyperemia, could not be proved. Bullock made the statement that cases of lupus with a high opsonic index gave better results with the *x*-ray treatment than those cases with a low index; he further stated that these latter cases, upon their indices being raised, also did much better. This did not seem to prove that the opsonins were responsible for this improvement, but that their estimation gave some indication of the resistance, whatever it might be, that was offered by the body against infection. If they considered then the opsonins as a measure, not of the immunity, but of the general resistance offered, they had a practical foundation to work upon. This foundation was possibly an empirical one, but it was the only one representing itself. Having defined this empirical position upon which their ideas rested, they might be permitted to approach closer to a practical consideration of the use of tuberculin as applied to surgical tuberculosis. In the combination of treatments, surgical and laboratory, they had always kept in mind this view-point, the improvement of the patient.

Vaccine Treatment of Surgical Tuberculosis.—Dr. Lewis L. McArthur of Chicago contributed this paper. Several years ago a series of investigations were begun to determine, if possible, the value of vaccine therapy in surgical tuberculosis. The tuberculo-opsonic index in the healthy individual was quite constant, 0.9 to 1.2. They admitted three things: (1) As a diagnostic method not invaluable; (2) as a therapeutic guide to vaccine dosage, not absolutely essential; (3) in the majority of cases it was useful in both, and, when feasible, should be utilized. Time for interference they believed to be when there was a high opsonic index. Dr. McArthur related his personal experience with tuberculin in various groups of surgical diseases. He did not wish to be understood as wishing to advocate the use of vaccines to the exclusion of other means. Active immunity in acute affections could only be secured when the opsonic index was used as a guide. In local tuberculosis it was impossible to secure results without it.

Infection of the Urinary Tract by Colon Bacilli.—Dr. Frank Billings of Chicago read this paper.

Dr. Charles N. Dowd of New York said that a great deal of observation concerning vaccine therapy hinged about the tuberculous lymph nodes, especially those of the neck. Good results might follow vaccine therapy. He agreed with all that was said regarding the advisability of using the vaccines in these cases, especially for one or two months before operation. The removal of the cervical glands of tuberculous nature did not require more than one-half an hour in children in the early stages of the disease, and in his experience he secured from 80 to 90 per cent. recoveries. Dr. Dowd had operated upon over three hundred children whose ages ranged from fifteen years down. Recurrences were not common. The glands could be removed without the slightest difficulty in the early stages of the disease; in the later stages healing was fairly prompt. He urged operation first and then, if desirable, the vaccine.

Dr. James A. McLeod of Buffalo said he did not wish to be understood as stating that surgery in the past had not produced good results in the treatment of tuberculous glands of the neck. But during the past years many cases had been referred to him with sinuses that persisted after operation. Besides, he had seen many cases with enormous scars. In many of the cases the question of operation had been eliminated by the preliminary inoculations with tuberculin. He believed that it was wise to give tuberculin injections for two or three months; then, if the desired effect was not produced, operate.

Dr. Lewis L. McArthur of Chicago acknowledged that when he had a case with tuberculous glands of the neck that could be removed by surgical means, he so removed them; but there were cases, for instance, where operation was refused, or cases that had been operated upon with a resulting fistula; these were the cases he treated with tuberculin, and with benefit.

Dr. Billings said that the colon bacillus infection of the genitourinary tract was a very frequent occurrence.

The Duty the Medical Profession Owes the Woman with Cancer.—Dr. Walter B. Chase of Brooklyn said that in view of the appalling fact that statistics of registration areas showed that one out of eleven of all women died of cancer, and that after reaching the age of thirty-five years the mortality increased to one in nine, and that as most of these were cases of uterine cancer, the question arose whether the medical profession did not owe an unfulfilled obligation to this most unfortunate class of sufferers. While large benefactions and well-organized efforts were ministering to the comfort of tuberculous persons, there was in this State no systematic humane plan to reach these more terrible cases, condemned to helpless suffering and torturing death. There was substantial basis for the belief that earlier recognition of the presence of malignancy in these cases would add something to the measure of relief to be obtained by radical or palliative treatment. Among these unfortunate women were large numbers whose resources make it impossible for them to secure proper medical advice or capable nursing. It was also painfully apparent that hospital facilities for incurables were entirely inadequate to meet the needs of society, not only in malignant, but other diseases. In view of these facts he offered a resolution to the effect that: First, that the Medical Society of the State of New York shall, by its president, appoint a committee of four, whose duty shall be to urge on all practitioners of medicine in this State greater care in making early diagnosis in case of suspected uterine cancers. Second, resolved, that this committee be directed to devise some method by which, along ethical lines, women may be properly informed as to the reason why they should seek early professional advice in menstrual and hemorrhagic disorders, and that they be further instructed to consider some more comprehensive plan whereby a general diffusion of appropriate and vital knowledge may be promulgated on this very important subject. Third, resolved, that this committee be directed to report its recommendations at the next meeting of the society. Fourth, resolved, that the treasurer of this society be directed to honor payment of bills incurred for printing and needful correspondence (if not otherwise provided for), and that this committee be empowered to fill vacancies in its membership and appoint sub-committees if deemed expedient.

Treatment of Pott's Disease.—Dr. Brainerd Hunt Whitbeck of New York read this paper. He spoke of the characteristics of Pott's disease upon which the treatment depended. The importance of early diagnosis was dwelt upon, and the responsibility therefore largely rested upon the family physician. The constitutional, and particularly the local, treatment was outlined. Cases were reported in which aspiration and the injection of Cabot's fluid were employed with good results. Tuberculous sinus was much to be dreaded. Beck's bismuth had been used in many cases, but with varying degrees of success. Leaving out of this mixture paraffin and wax had been followed by better results. The progress in the treatment of these sinus cases was very slow at first. Fresh air in large doses was of inestimable value in the treatment of cases of Pott's disease.

Then followed a symposium on appendicitis, under the auspices of the New York Surgical Society.

Appendicitis in Children.—Dr. Charles Dowd of New York said that surgery in children differed from surgery in adults in many particulars. The osseous and lymphatic systems, especially of the thorax and abdomen, showed very marked peculiarities. In children attacks of appendicitis differed from the disease as it occurred in adults. His paper was confined to a consideration of two questions: First, when to operate, and, secondly, how to operate. The ordinary symptom which was so misleading in children was muscular rigidity; that, taken in connection with a long appendix, often complicated the location of this symptom. Appendicitis should be differentiated from a beginning pneumonia, and a general peritonitis from an unknown cause, from a tuberculous pneumococcus, and gonococcus peritonitis, from coxitis, and cyclic vomiting. The results obtained in these cases of appendicitis in children depended upon the condition of the patients when they were referred to the surgeon. Dr. Dowd reported 181 cases which he divided into three groups, according to time; before 1905, 70 cases; 1905-1907, 50 cases; 1907-1909, 61 cases. The percentage of the cases operated upon within twenty-four hours of the onset in the first group was 15.7 per cent.; in the second group was 16 per cent.; in the third group was 36.1 per cent. The mortality in the first group was 10 per cent.; in the second, 8 per cent.; in the third group, *nil*. There were more young children in the last group than in the other two groups. The simplicity of operation was more marked in the late than in the early group. The local abscesses were drained to the neglect of the general peritoneal cavity.

Masked Appendicitis.—Dr. George E. Brewer of New York called attention to certain types of cases grouped under the term "masked appendicitis," which he said could be illustrated only by the recital of case histories. Errors in diagnosis were fraught with dire disaster. Dr. Brewer had made the mistake in diagnosing appendicitis when many other conditions existed, and he related the histories of some of them. He also called attention to some of the conditions chronic appendicitis might simulate, which he illustrated by the relation of case histories.

When to Operate in Appendicitis.—Dr. Joseph A. Blake of New York presented this paper, which was read by Dr. McWilliams.

Conditions Simulating Appendicitis.—Dr. Alexander B. Johnson of New York read this paper and offered the following conclusions: (1) A very large number of conditions might simulate appendicitis. (2) Many of them when carefully studied, especially with regard to the past history and present signs and symptoms, would render a differential diagnosis possible. (3) In acute cases, with an imperfect history and an inability to observe the patients during the earlier hours of the disease, an accurate diagnosis might be impossible. This would be especially true (a) of perforating lesions of the alimentary tract other than appendicitis; (b) of some affections of a tube and ovary upon the right side; (c) of cases of well developed purulent peritonitis; (d) in the erythema group, Henoch's purpura, with abdominal symptoms, might so exactly simulate acute appendicitis that no differential diagnosis was possible during the earlier hours of the disease.

Analysis of Fourteen Hundred and Eleven Operations Upon the Appendix.—Dr. Clarence A. McWilliams of New York read this paper, which was a report based upon all the operations performed at the Presbyterian Hospital during the past four years. There were in all 1411 cases, of which 687 were acute, 512 chronic and relapsing, and 212 in which the appendix was removed in association with other primary procedures. The sexes in 1199 operations for acute and chronic appendicitis were about equally represented, though the milder and more chonic inflammations occurred more commonly in females. In 512 chronic cases 62 per cent. occurred in females. In severe inflammations the disproportion between the sexes was less, 57 per cent. being females. In 595 operations for severe acute lesions, 37 per cent. only occurred in females. One sex did not seem to be more disposed to a fatal issue than the other. About one-third of the cases occurred in patients under twenty years of age, and a trifle over two-thirds were in patients under thirty. The extremes of life withstood the disease badly. There were 16 patients five years of age or under, with a mortality of 18 per cent. The author attributed this high mortality to the difficulties of making an early diagnosis in young children. In nine patients over sixty years of age the death rate was over 62 per cent. He believed this was due to delay in the endeavor to tide the patient over acute attacks. This was a more unsafe course to take with elderly than with younger patients. In the 1411 cases the mortality was five per cent.: in 512 operations for chronic and relapsing conditions the mortality was 0.05 per cent.; one fatality was caused by the slipping of a ligature from the stump. Additional burying of the base of the stump seemed safer. For the 687 operations performed in the presence of acute conditions the mortality was 9.8 per cent. He discussed the pros and cons of early operation, that was, for those performed during the first forty-eight hours, intermediate operations, those from the third to the sixth day, inclusive, and late operations, those performed after the sixth day. He stated that the operators at the Presbyterian Hospital answered the question as to whether to operate in the intermediate or dangerous stage with a decided "Yes." Their statistics were made up of cases where there had been no delay in operating in all stages of the disease. It was instructive to examine the acute cases in regard to the relations of presence or absence of previous attacks, and the durations of the disease at the time of operation as to the prognosis. In 647 acute cases over one-third had had one or more previous attacks. The milder the lesion, the more likely was the patient to have had one or more previous attacks, while the severer, the less likely. In the acute catarrhal cases, over one-half had had previous attacks, while of those with the severest lesions only about one-fourth had had previous trouble. Of the fatal cases, only one-seventh had had previous attacks. Of the patients with acute inflammations who had had previous attacks, the recurrences took place in about one-third within six months, and in almost two-thirds within one year. In twenty of their cases operation was performed within sixteen hours of the beginning of the symptoms; only one died, and that as the result of an acute pericarditiis on the ninth day. The abdominal condition at the time was entirely satisfactory. Commonly operations performed within sixteen hours of the onset resulted in no mortality. Of 115 cases operated upon between the sixteenth and twenty-fourth hours, the mortality was 3.4 per cent. Three of these fatal cases had diffuse peritonitis with gangrenous appendices. These fatal cases brought out the fact that, operate as early as one might, there was still certain to be a small mortality. There were 145 cases operated upon on the second day, with a mortality of 6 per cent. Of 103 patients operated upon on the third day, 8 per cent. resulted fatally. Operations upon the fifth and sixth days were equally fatal, showing a mortality of 14 per cent. The combined mortality of operations from the third to the sixth day was 12 per cent. The patients operated upon from the seventh to the tenth day gave a mortality of 20 per cent. This showed that early operations and operations made during the intermediate dangerous period gave better results than were obtained by waiting. Dr. McWilliams related three cases, all resulting fatally, in which the Ochsner treatment was employed. Such experiences had discouraged them in the use of this treatment.

As to complications, pregnancy was a coincident condition in six cases, four of whom were pregnant four months or less; none of these died or aborted. Two patients six months pregnant died. Pregnancy was a serious complication urgently requiring early operation. Pulmonary embolism occurred four times with three deaths. Intestinal obstruction was a particularly fatal complication. Ileostomy for paralytic ileus was performed in twelve cases, ten of whom died, or 83 per cent. Fecal fistula developed in twenty-six cases, or in 3 per cent. of the acute operations, with three deaths not attributable to the fistula. The less handling of the intestines at the time of operation, the less liability there was to this complication. Dr. McWilliams was of the opinion that removal of the appendix in association with other primary procedures did not increase the mortality.

Appendicitis.—Dr. Roswell Park of Buffalo said he only wished to make some desultory remarks on the subject of appendicitis, including some of the mooted questions on what to do and what not to do when called upon to attend such cases. The appendix should be regarded as a shut sac within which were enormous possibilities for toxemic disturbances. Dr. Stockton had called his attention to another thing, suggesting the possibility of treating appendicitis with vaccines. This suggestion was brought about by the knowledge that there was in this disease a lowered resistance, and the question arose, could they not improve this very much by the same sort of vaccine therapy talked about at the morning's session. No one, however, would think for a moment of substituting such a treatment for the operative in acute cases; but in the chronic cases the question as to the value of vaccine therapy might be raised very properly. It might become a very valuable adjunct to surgery. He thought that one of the most striking features in connection with cases of appendicitis was the varieties of views held by different men and the varieties of advice given to patients by them. Why did such a difference of opinion prevail? Dr. Park ascribed it to the fact that physicians did not come in contact with the physical and pathological side of the disease; they neither saw nor handled it. This was equally true of gall-bladder disease. In two-thirds of the cases where the physician called in the surgeon, the former was not present at the operation, and therefore he failed to see the conditions as they actually existed; he rarely saw a case of appendicitis in its true aspect. The operator too was at a loss at times to account for the conditions revealed. It was the rule in good surgery that the fewer hands introduced into the abdominal cavity, the better for the patient; but it would be very helpful to the physician if he was permitted to see just what the operator felt and saw; but to allow him to introduce his hand into the abdominal cavity to feel and investigate would probably in many instances mean the death of the patient. Everything should be left to the surgeon. An interesting question related to the relationship of appendicitis to typhoid fever, as well as to perforation, to thrombosis, to deep phlebitis, and other possibilities of typhoid fever. There were reported many cases where an acute mesenteric thrombus had been mistaken for perforation, the mistake only being discovered at autopsy. Then there were, no doubt, many such cases concealed because no autopsy was performed.

Dr. Edwin M. Stanton of Schenectady objected very seriously to the 18 per cent. operative mortality, and quoted largely from the statistics given out by the Berlin Medical Society, the most valuable of any concerning appendicitis. He also told of his experience with the Ochsner treatment, which he advocated.

Dr. Robert T. Morris of New York said that some of them could remember when the diagnosis of "inflammation of the lungs" was a commonly accepted diagnosis. The diagnosis of "appendicitis" was not more definite. That had caused the varieties of opinion on the subject. He believed that they were often talking about different things when using the name appendicitis. There were at least four kinds. Intrinsic infective appendicitis called for operation so soon as the diagnosis had been made. They could not use judgment in the matter because they did not know just what the bacteria were going to do. The subject lay outside of the limitations of judgment. In the other three kinds of appendicitis, namely, with extrinsic infection, syn congestive appendicitis, and fibroid degenerative appendicitis, they could use judgment and, in the latter two kinds, seldom needed to operate at all.

Dr. A. Jacobi of New York expressed his satisfaction in listening to the number of papers read by the surgeons, because it proved to him that they were not only operators but thinking physicians as well; they all gave something about diagnosis. With regard to Dr. Park's remarks, he did not think the general practitioner was as bad as he tried to make out; most of the busy practitioners could not be present at the operations, and they should not be blamed for not being better acquainted with the actual existing conditions. Dr. Jacobi thought it would be well if they had not only statistics of the cases operated upon and those that came to the autopsy table, but they should have statistics on diagnosis. Dr. Brewer stated that he had made fifteen or more mistakes in diagnosis, thus showing that even the masters in the science and art of surgery made mistakes. He wished they had statistics on mistaken diagnoses; it might justify the mistakes made by the general practitioner. Dr. Jacobi recalled a statement made by one of the foremost surgeons in this country; he said that it was very often a very difficult matter to make a diagnosis of appendicitis. Young children were very much disposed to attacks of this disease; a small infant had a great many more lymphatic vessels and ducts than had an adult; moreover, there were plenty of opportunities for an accumulation of lymph bodies in the infant. The length of the appendix in the infant was one-tenth of the colon, whereas in the adult it was one-twentieth. In the infant the shape of the appendix was more funnel-like, and in many cases there was a constriction. There were many reasons why the small child should have appendicitis. In closing, Dr. Jacobi said that if the masters in surgery would teach the general practitioner how to make a correct diagnosis, they would not have so many opportunities to blame him for not calling on them in time.

Dr. William W. Skinner of Geneva called the attention of the society to the little point in diagnosis which he considered of great importance, and which had helped him in a great many instances. In the neighborhood of the infection there was a certain amount of darkening of the contents of the veins; in cases of appendicitis, a careful examination of the skin over the abdomen, especially when the skin was stretched, which would increase the translucency, would reveal over an inflamed appendix the veins well darkened compared with other veins in that region of the abdomen. The veins that showed this darkening were those just internal to the anterior superior spine of the ilium which ran upward.

MEDICAL SOCIETY OF THE COUNTY OF NEW YORK.

Stated Meeting, Held December 27, 1909.

The President, Dr. H. Seymour Houghton, in the Chair.

Local Anesthesia in General Surgery.—Dr. Winfield Scott Schley read this paper. (See page 225.)

Dr. Alexis V. Moschcowitz divided the indications for the use of local anesthesia into two classes, general and special. It was true that both merged one into

the other so very gradually that it was hard to draw the line where the general indications ended and the special indications began. Among the general indications, however, were the various disturbances of metabolism and diseases of the heart, lungs, kidneys, liver, etc. Among the special indications for local anesthesia was to be mentioned especially disease of the thyroid gland. He said that he had had occasion during the past two or three years to operate upon a number of cases of disease of the thyroid gland and all were done very successfully under local anesthesia, with but little trouble to the patient, but with some additional trouble to the surgeon. Dr. Moschcowitz did not believe that operations for the radical cure of hernia should be attempted under local anesthesia unless there was some distinct contraindication to general anesthesia. He had always taken the stand that if a patient had made up his mind to be operated upon for hernia the best chance should be given him for a radical operation and a radical cure, and a far better guarantee was given him if the work was done under a general anesthesia and not under a local one. A little less than two years ago he operated upon a colleague for a recurrent inguinal hernia. This colleague had been operated upon previously by one of the best surgeons in the city, and he used local anesthesia. In a letter received by Dr. Moschcowitz recently this colleague stated that the more work he did with local anesthesia the more and more did he come to the conclusion that one could not do good radical work in hernia operations under local anesthesia.

Dr. John H. Branth said that his experience with cocaine for local anesthesia in minor surgery dated back more than fifteen years. Knowing of the effects of cocaine upon the conjunctiva, he applied it for a toothache on himself, but it did not stop the intense agony; he then decided to try a hypodermic injection of this agent along the root of the tooth and inside of the alveolar process. The relief was immediate. On attempting to withdraw the needle, however, it broke and he had great difficulty in removing the broken end. The region was entirely devoid of sensation. He then applied the forceps, rocked the tooth slowly until he succeeded in extracting it. There was very little hemorrhage. Soon he began to feel the systemic effect of the cocaine. He had a profuse perspiration, a very rapid pulse, and he felt as though he was walking in air. His thoughts swept in a short time over his past. Dr. Branth said that he had an idiosyncrasy for morphine and quinine, and he thought that cocaine should now be included. From that time he pulled his own teeth when necesary. Rocking the tooth for perhaps a minute enabled him to save the alveolar process from fracture and the tearing of the gum; it left a small wound that healed quickly and left a good base for an artificial dentine. He then began to make experiments with cocaine, and he found that solutions very much weaker than the usual 4 per cent. or 10 per cent. produced the desired anesthetic effect. He had removed a lipoma of the shoulder weighing three-quarters of a pound with a solution of one-fortieth of a grain of cocaine and one-twentieth of a grain of eucaine in one ounce of water; this he did in a woman who had a valvular heart disease and chronic bronchitis. All of this solution was not used. The same solution he used for circumcision, placing a rubber band around the penis to prevent the systemic effect. The tissues of the penis became white and bloodless, an advantage for the operator. He said he had made numerous experiments upon his own body and on many patients for minor operations with these solutions, and he found that it produced the desired anesthesia and had no untoward effects. In closing his remarks he described the sensation caused by cutting his own flesh. He had a deep carbuncle on his thigh, and he decided to make a free opening and cut out the indurated part. When cutting through the skin it felt as though it was an inch or more in thickness, and there was a creaking sensation as though he was cutting into a pineapple or leather. This he attributed to the systemic effects of the cocaine. Cocaine should be used with great caution; very small doses sometimes give rise to alarming symptoms, but the small doses he advocated would promote safety.

Dr. John F. Erdmann admitted that all that was claimed for local anesthesia by Dr. Schley was true, but the question that arose was the difference between cases, and should they admit that a great many cases could be done under local anesthesia, but should they be done? And if so, in what kind of cases? In operating upon thyroids he said that the records of St. Mary's Hospital of Rochester, Minn., where ether used showed no deaths as the result. Dr. Erdmann had one death from hyperthyroidism seven years ago; in this case he made the mistake of removing the entire gland. In this instance death was not due to the ether administered, but to the fact that he removed the entire gland; the result would have been the same under cocaine. With regard to operations for hernia, he knew of at least fourteen recurrences in cases that had been operated upon under local anesthesia, and the operations had been done by one of the best surgeons in this line of work in New York City. To be sure, operations upon the gall-bladder, common duct, appendix, pancreas, and other organs could be done under local anesthesia; but if his own abdomen was to be opened for a cholecystectomy or a cholecystotomy he would insist that ether be given and not cocaine or other local agent.

Dr. Parker Sims believed that a great deal of surgical work could be done under local anesthesia. But it was not a question of what could be done, but of what should be done under local anesthesia. He believed that it should be reserved for a very limited field of usefulness. In hernia and other similar operations he did not believe that local anesthesia should be used, unless there were strong contraindications to the use of general anesthesia. In cases of strangulated hernia, with regurgitant vomiting he believed that local anesthesia should be employed, because of the danger of suffocation, in such cases, attending the use of a general anesthesia. While we recognize the limited usefulness of local anesthesia, he said that we should feel thankful to Dr. Schley for again bringing the subject to our notice, and for the improvement in technique which had been brought out.

Dr. Schley said that the object in writing his paper was not only to show what an improved technique could accomplish, but to show also the restrictions to the use of local anesthesia. At present its greatest usefulness was in those cases where general anesthetics greatly added to the risks or were prohibitive, but it had arrived at that stage of perfection where it could be extended to many cases able to take general anesthesia to insure a more agreeable and safer postoperative period. Those who tried to use local anesthesia in all surgical cases would get into trouble. This was a field in itself and various successes would attend its use. In operations for goiter and especially exophthalmic goiter it was the anesthesia to use. While in Berne he had seen Prof. Kocher operate upon over thirty such cases, and none was done under a general anesthetic; these cases were both struma goiter and exophthalmic goiter. Up to that time over 3,000 oper-

ations upon goiter had been done there and nearly all under local anesthesia, which was used as a routine in these cases. At the same time Dr. Schley said that the extent to which spinal and local anesthesia were carried abroad should not be followed in this country without reserve. Local anesthesia with those who could use it and in properly selected cases could often accomplish brilliant results.

Serological Aspect of the Diagnosis of Syphilis.—Dr. Hideyo Noguchi, after giving the principles of the Wassermann reaction, gave a description of the different methods as heretofore proposed. He considered each critically from the serological viewpoint. He laid special stress on the fact that active human sera should not be employed when the preparation serving as antigen contained proteins, such as peptone, albumose, nucleoprotein, and many other cleavage products, because the latter produced complement fixation with nonsyphilitic specimens. This nonspecific reaction did not take place when the antigen preparation was based on pure lipoids, as was the case with Dr. Noguchi's method, or when the sera were previously inactivated. Dr. Noguchi presented an analysis of about twenty-two hundred cases of syphilis and about six hundred cases of metasyphilis, showing the results obtained with his method by different investigators.

Serodiagnosis in Syphilis. A Classification of Clinical Observations.—Dr. Victor C. Pedersen read this paper. Dr. Noguchi had carried out certain observations in collaboration with Dr. Pedersen and did the compdement-fixation by the Wassermann method up to about December 31, 1908. The Wassermann-Noguchi test had been used ever since January, 1909. The Noguchi method of estimating the globulin content of the blood serum had been used since the outset of these investigations regularly up to March, 1909, more or less as a control of their work. In order to fulfill the hope of tracing the progress of this test, Dr. Pedersen's records had been divided into certain classes, and the classification submitted for the series of observation closely followed the original designation of Ricord for the stages of syphilis. As to the general status of serodiagnosis, the following résumé was presented. In a scientific matter of such a recent discovery and comparatively speaking of limited development, he did not believe that one could properly speak of conclusions. He thought, however, that the following might be given as suggestive thoughts. These serum reactions could not be regarded as expressions of immunity; otherwise there would be a certain number of natural immunes discovered. This matter of immunity, as shown by the serum tests, was early suggested by various authors, but was soon abandoned. Serum diagnosis might present a certain index as to susceptibility, as was suggested by the fact that its variations corresponded with those of severe infectious and destructive lesions rather closely and, in certain cases, proceeded, notwithstanding the treatment, exactly as the clinical symptoms did. The occurrence of a positive test in such diseases as yaws, malaria, leprosy, and scarlatina did not materially discount the value of the observations in syphilis because leprosy, yaws, and malaria were exotic affections and because in scarlatina the reactions were transitory and were not uniformly present. Dr. Pedersen said that one could not properly diagnosticate the presence of syphilis by a positive test alone, no matter what might be the period of the disease, unless there were other potent factors present corroborative of the test as such. Conversely, a negative test could not itself exclude syphilis. Under certain circumstances the negative test was of value. As to serodiagnosis in chancre, Dr. Pedersen said that chancre cases without an examination for spirochetes, which gave a positive serum test were possibly syphilitic; of course, if the chancre was typical and the glands were typical, the case became probably syphilitic. Chancre cases with a positive spirochete examination were corroborated by a positive serum test. In each of the foregoing a negative test meant nothing, just as the absence of other symptoms during the chancre stage meant nothing. The positive combined spirochete and serum test indicated active abortive treatment. A positive test after thorough treatment indicated a clinically supervening relapse. A positive test during proper treatment, and notwithstanding treatment, probably meant an incurable case. A positive test after cessation of treatment, and after a preceding negative test, probably meant a relapse. A positive test in the absence of symptoms meant at least that the patient had had syphilis, and possibly that he had it still in the sense that a relapse might appear, or, according to Müller, that active syphilis was present. In latent syphilis a positive test demanded treatment. A positive test did not mean that the active, existing lesion was necessarily syphilitic, but rather that a syphilitic basis existed in the system. This was similar to the effect of antisyphilitic treatment on lesions, success with which did not necessarily mean that the lesion was syphilitic. In general the older the case, the more valuable did the positive reaction become. A positive reaction also depended on the extent and activity of the infection. A positive test might be regarded as an active symptom, and, like any other active symptom of syphilis, to indicate treatment. A strongly positive test, with many symptoms, almost invariably indicated a strong infection and great susceptibility. Weak and moderate reactions during the treatment, and as a reduction of a previous positive reaction, probably showed a decrease in the attack and might be a guide to treatment, variable, like other guides, such as general condition, emaciation, weight, strength, etc. In latent syphilis, weak and moderate reactions were of great importance, when the diagnosis was proven. Negative tests were equivocal and uncertain. The danger of a negative test lay in the sense of false security which it gave. A negative test following a preceding positive test and thorough treatment possibly indicated a decrease of the disease, but it did not mean absence of the disease, any more than did absence of clinical symptoms in the same circumstances. A negative test during treatment, and in the presence of active symptoms, was inexplicable, but it was occasionally found, as shown by several cases in the author's report. A negative test after cessation of symptoms and treatment, and consistently persisting in response to repeated investigations through a long time, became progressively a favorable sign, precisely like the continued absence of clinical symptoms of the disease. A negative test after long treatment and during a relapse was confusing, but certainly did ocasionally occur. A rapidly induced negative test followed energetic treatment. Might this not be regarded as an indication to reduce the activity of the treatment? Yes, provided only the clinical symptoms agreed. There seemed to be an inconstant and uncertain relation between the test and treatment, probably because they knew so little about the nature of the conditions in the blood giving the test and possessing, perhaps, too little reliable index of any kind for treatment. In recent cases the test was more influenced by treatment than in later cases. Remedies which cured syphilis, acting thereby on the virus, influenced the reaction notably and relapses were

always accompanied by a return of a positive reaction. These truths could not exist without an assignable influence of the test on treatment. Serodiagnosis could not be very definitely relied on to indicate treatment unless one was following the repeated appearance and disappearance of positive tests in a given old relapsing case. Here the positive test might forerun the clinical relapse and thus become recognizable as an indicator of resumption of treatment. Finally, the cycle of syphilis could not be regarded as completed in much less than five years; namely, from two to three years of treatment and the remaining years of periodical observation thereafter. This test was approximately three years old, and it was therefore folly to try to talk about its bearing on prognosis as a whole. Prognosis could hardly be declared clinically in less than five years of treatment and observation combined. In certain cases the test was of undoubted value in suggesting the outlook for the patient. A test which persisted during treatment or which was found present in known latent cases was undoubtedly of unfavorable meaning. The more precise limits of this dictum would be determined as the years went by. An induced negative test which remained negative after frequent trials and was accompanied by absence of clinical signs was, of course, accumulatively good evidence of cure. A returning positive test precedent to or accompanied by clinical evidence of the disease was not a hopeful condition and might be of value in tertiary, especially cerebrospinal syphilis.

Demonstration of the Noguchi Complement-Fixation Test.—Dr. Howard Fox made this demonstration and discussed some of the points of difference between the Wassermann and Noguchi tests, showing the advantages possessed by the Noguchi method. In the system of Wassermann sheep's corpuscles and anti-sheep amboceptor were used, while in the Noguchi system human corpuscles and anti-human amboceptor were employed. The chief theoretical objection to the use of sheep's corpuscles was the fact that the patient's serum contained natural amboceptor for sheep's corpuscles. This natural amboceptor, in addition to the immune amboceptor which was used for the test, was often excessive enough to give a negative reaction when a positive reaction should have been obtained. Another advantage of the Noguchi method was that the patient's serum might be used either in active condition, or after being inactivated, *e.g.* heated to 56° C. for half an hour. A practical advantage of the method was that two of the substances used, namely, the antigen and amboceptor, had been impregnated in paper, so that small pieces of the paper represented measured amounts of the fluid substances. In performing the test the following five substances were required: (1) Serum of the patient, one capillary drop, or about 0.02 c.c., if used in active state; four times that amount, if used in inactivated condition. (2) Complement, 0.04 to 0.05 c.c. of fresh guinea pig serum. It was possible, though not advisable, to use the complement in paper form. (3) Corpuscles, 1 c.c. of a 1 per cent. suspension in physiological salt solution of normal washed human corpuscles. (4) Antigen. One square of paper representing a measured amount of acetone-insoluble lipoids (protein free). (5) Amboceptor. One piece of paper representing two units of anti-human amboceptor. The first four substances were placed in small tubes in the order named (for the sake of convenience). The tubes were then shaken and placed in a thermostat for one hour, or a water bath for a half hour at 37° C. The amboceptor was then added, the tubes shaken, and again placed in the thermostat or water bath. Hemolysis was generally complete in from one to two hours, after which the results were read. Dr. Fox discussed the control tubes that were necessary, and he exhibited a series of tubes previously prepared, showing the completed reaction. A complete demonstration of the Noguchi test with fresh materials was then given.

WILLIAMSBURG MEDICAL SOCIETY.

Stated Meeting, Held January 10, 1910.

Dr. Joseph Merzbach in the Chair.

Presentation of Specimens of Four Unusual Cases of Appendicitis.—Dr. M. Lederer, in the absence of Dr. S. R. Blatteis, presented these specimens. One of these had shown typical lesions of tuberculosis, such as tubercles, giant cells, necrosis, and infiltrating all the walls had been evidences of acute suppurative exacerbation. The second specimen was that of an irregular mass 7 by 5 cm., containing five stones, weighing in the aggregate 5 gms., and composed of a crust of calcium and magnesium salts and a center of amorphous material. The third specimen contained a pin 3.5 cm. long and covered with a blackish deposit. The fourth specimen was that of adenocarcinoma of the appendix. It had been removed from a patient, aged 30, who had died one day after admission to the hospital. Four days before this he had developed pain in his abdomen and the subsequent history had been that of the usual suppurative appendicitis. There had been no history or evidence of malignancy in any other part of the body.

Report of a Case of Purpura Complicating Measles.—Dr. Joseph Krimsky of Brooklyn read this paper.

The Treatment of Locomotor Ataxia.—Dr. Graeme M. Hammond of New York read this paper. He said that he would confine his remarks to only certain phases of the treatment. Years ago this disease had been considered an inflammation. In combatting this they had used the actual cautery, ergot, heat, and cold. Later it was looked upon as an incurable affection. Still later, when syphilis and tabes had been clearly associated, there were used large doses of antisyphilitic remedies. In certain cases of acute syphilis of the cord there was a syphilitic exudation into the posterior portion of the cord. In these cases good results had followed the use of antisyphilitic remedies. But these cases were not cases of locomotor ataxia any more than fracture of the spine. Of later date the neuron theory gave a clearer idea of the disease. It was now believed that locomotor ataxia was a degeneration of the sensory neurons, beginning in the cells of the ganglia of the posterior roots, with a secondary degeneration of the sensory neurons. In many instances one had to do with a meningitis with compression on the posterior roots. Not all cases were the same. Some cases had no pain, and some had considerable pain. Some cases could not walk at all; there were others that had considerable ataxia, and there were some cases in which there was hardly any ataxia. The speaker cited the case of a professional dancer with Argyll-Robertson pupils and absent knee-jerks, whose ability to dance had not been interfered with. The speaker had received his cue in treating locomotor ataxia by means of large doses of strychnia, from the experience of Dr. Dana in treating tic douloureaux with this drug. In the latter condition the pains in the face were sharp and lancinating, and were quite analogous to those pains in the legs that were common in tabes. Dr. Dana had been able to arrest these pains by means of strychnia in doses of 1-16 to 1-12 of a grain three times a day. It had occurred to the speaker that these results might also follow if this treatment were pur-

sued in locomotor ataxia. He had had ten years of experience with this method of treatment. Its efficacy depended upon the fact that strychnia had a primary effect upon the cells of the cord. He began with the internal administration of a tablet of 1-30 grain three times a day. This was increased within one week to 1-20 grain three times a day, and in another week to 1-16 grain three times a day. Then by using a solution of strychnine of one grain to the ounce, and adding to the last dose (1-16 grain) one drop of this solution, and increasing the dose by one drop each day, he was able to gradually increase the dose of strychnine, so that at the end of a month the patient got 1-8 grain three times a day. The patient was then given two tablets of 1-16 grain each three times a day and this dosage was kept up for two months. This was then increased with the drop dosage until the patient got three tablets of 1-16 grain each three times a day. This was kept up for two or three months, and then increased until the patient got 1-4 grain three times a day. At first he had given this dose hypodermically once a day, but he had found this to be of no advantage. There were cases in which the treatment had been continued for from five to seven years, and then the strychnine was withdrawn gradually. The result of this treatment was that in the majority of cases no increase in the disease had occurred. The speaker had never seen a case in which the Argyll-Robertson pupil had disappeared, or the knee-jerk had returned, except in one case in which the latter was absent for one week. The Romberg symptom never disappeared. It made no difference to the patient whether the Argyll-Robertson pupil disappeared or the knee-jerks returned, so long as he felt better and his disease was arrested. Other methods of treatment were also serviceable. The Frankel movements reeducated the muscular centers. Frankel's statement was that the patient's eyesight was reeducated. It was surprising how the patients succeeded in getting control of their movements. As regards diet, the patient was to eat ordinary things in moderation. Outdoor life and exercise in moderation were to be advised. Many physicians advised keeping the patient in bed, but the speaker got him out of doors early. The patient was to be told that his sexual life would end early; otherwise he would worry. He was not to be given potassium iodide, nor bichloride, nor rubbings. The speaker had seen cases of strychnine intoxication in the hands of others; the reason was that the dose was increased too rapidly. Strychnine was not serviceable in sclerosis of the lateral columns. It was of no benefit in the advanced cases in which they could not walk, nor in cases in which there was atrophy of the optic nerve.

Dr. Jos. Fraenkel of New York said he would not agree to the expression "treatment of locomotor ataxia." Locomotor ataxia was a multitude of diseases. There were many theoretical conceptions of the disease; this was an eternal clinical and therapeutic fact. Neurologists had been looked upon as the specialists of incurables. The speaker had seen three cases of locomotor ataxia perfectly cured. These cases had also been observed, and the cure attested by Dr. Dana. The speaker stated that he had lived for nine years in an institution in which there had been on an average thirty tabetics per day, and he had learned to recognize in a subject of locomotor ataxia an individual who had some disease of the cord. He was able to differentiate the following three forms: 1. The cranial form; this was also called the optic or meningeal form. In this variety the patients experienced dizziness and ringing in the ears. This group of cases was free from all the usual crises, pains, ataxia, etc. This group included those cases in which optic atrophy occurred within the first year or year and a half of the disease. 2. The visceral group, characterized by the early appearance of visceral symptoms, such as gastric crises, which frequently simulated cases of locomotor ataxia. 3. A group characterized by the presence of cerebrospinal symptoms, such as shooting pains, and the absence of visceral symptoms. Erb had stated that every case of tabes was syphilitic. The speaker had seen cases of tabes that had been made worse by specific measures, and had seen two cases that had been made better. In discussing the efficacy of specific treatment it was necessary to recognize two groups of cases: First, those showing no trace or evidence of inflammation anywhere in the body, but presenting a change of neural tissue for connective tissue; second, a group including cases of posterior meningitis, posterior lymphangitis, posterior exudation, and specific leptomeningitis. In the former group one was practically dealing with the old type of Duchenne, which had nothing to do with syphilis, or with syphilitic exudation in the posterior columns or around the posterior columns. Duchenne's type was due to exhaustion, and was analogous to the form of disease resembling tabes that had been produced by Edinger experimentally in rats, by causing the latter to run around in a treadmill. The metasyphilitic group of cases was to be distinguished from the first group by the fact that the symptoms of the former had a marked irregularity. The true Argyll-Robertson pupil was found only in the Duchenne group; it was a pupil consisting of a bilaterally equal miosis, irresponsive to light but reacting to accommodation. In the second group there were pupils of all kinds and degrees of irregularity. There was still a third group of cases characterized by the evidence of some definite area of the spinal cord affected by some meningeal exudate. The first group and the first part of the second group were made worse by antisyphilitic remedies. In this connection the examination of the cerebrospinal fluid for the Wassermann reaction was important. The speaker believed that Dr. Hammond's method of treatment was good in selected cases of the nonexudative type. He did not favor the use of the Frankel movements, for these increased the element of fatigue, which hastened the degeneration in the motor ganglia.

Philadelphia County Medical Society.

At a stated meeting, held January 12, Dr. Ellen P. Corson-White read by invitation a paper entitled "Demonstration of the *Treponema pallidum* and of the Serum diagnosis of Syphilis (Wassermann Reaction)." She pointed out the specific diagnostic significance of the presence of the treponema in suspicious lesions and she dwelt upon the great value of the hemolytic serum reaction in the differentiation of syphilitic and parasyphilitic as against nonsyphilitic disorders. She demonstrated the technique of the reaction and she related the results of her observations in a considerable number of cases. She had found the original Wassermann reaction entirely trustworthy in the matter of positive responses, but the Noguchi modification the more so in the case of negative responses. Dr. Hideyo Noguchi of the Rockefeller Institute for Medical Research discussed some of the changes that he has made in his modification of the Wassermann test as the result of a more extended experience. He has subjected the procedure to a most critical scrutiny in a large number of cases, syphilitic and otherwise, at the hands of many different observers, and he has thus been able to demonstrate

its practicability and its trustworthiness. Dr. B. Sachs of New York by invitation read a paper dealing with "Newer Diagnostic Methods in the Study of Diseases of the Central Nervous System." He pointed out the great utility of the demonstration of lymphocytosis of the cerebrospinal fluid obtainable by lumbar puncture in the diagnosis of active syphilis. A considerable experience has also demonstrated the usefulness of the Wassermann reaction in the differentiation of syphilitic and parasyphilitic disorders from nonsyphilitic affections, and the therapeutic indications resulting therefrom. Dr. Homer F. Swift of New York City pointed out that the serum reaction could be looked upon only as any other symptom, and that its invariable presence in every case of syphilis could not reasonably be expected. In order that the results of different investigators may be intelligently compared it is necessary that there should be some approach to a standardization of the reagents used. Dr. Wm. G. Spiller cited a number of instances in which the information gained by the employment of the reaction decided important points in diagnosis, prognosis, and therapeutics.

The Leucocyte Formula in Variola.—Alfonso Montefusco says that in variola the leucocyte formula is changed in a way which differs from that present in other acute infections. Instead of the polynuclears, the mononuclears are increased. This change begins with the beginning of the disease and ends when the crusts have fallen. The mononuclears are in the proportion of sixty per cent., and include both small and large cells and a small number of lymphocytes. Forms analogous to the neutrophile myelocytes are also found. The polynuclear eosinopiles diminish toward the end, while they are increased in the beginning. In a recent epidemic of smallpox the author examined the blood in fourteen cases. He found that the polynuclear neutropiles are diminished in all forms of the disease. The polynuclear eosinopiles are increased up to eight and a half per cent. in the ordinary forms of smallpox. The mononuclears increase from eight to eighteen per cent. in the hemorrhagic form, and to forty per cent. in the ordinary form. There is a special relation between the increase of the mononuclears and the severely clinical form rather than of the suppurative process. The lymphocytes presented a constant increase in all forms of the disease; the same is true of the myelocytes. The leucocyte formula is characteristic in its general lines, but is not sufficiently different from other diseases to enable us to make a differential diagnosis by means of it.—*Giornale Internazionale delle Scienze Mediche.*

Bismuth Poisoning.—In concluding a report of several cases of poisoning from the use of bismuth subnitrate, V. C. Davis and T. R. Kauffman say: Poisoning from bismuth subnitrate vaselin paste is more common than we had supposed. Since the report of these cases, in an examination of about twenty-five orthopedic cases in the Cook County Hospital in which bismuth had been injected into their tuberculous sinuses more than once, we found that in six cases there was more or less pigmentation of the gums. In one of the cases extreme blue pigmentation was present on the gums, lips, and the cheeks without subjective symptoms. From this we have reason to believe that pigmentation of the gums is an early sign of bismuth intoxication and should be taken as a signal to at least discontinue the administration of the paste. In the reported cases four of the five received six ounces or less at the first injection and ten ounces or less *in toto*. One fatal case occurred after the use of less than one ounce of the paste. Toxic symptoms developed after the first injection which might influence poisoning, as some of these cases were not skiagraphed after the paste was used. There are acute and chronic cases of bismuth poisoning, the former being fatal with general symptoms and the latter tending to a slow recovery with practically only local manifestations, but the onset of both types is very much the same. Thus far no case of pure nitrite poisoning following the use of bismuth subnitrite paste is on record, and, though there is but one case where the nitrites played a part in the poisoning, it seems that danger should be avoided by the use of bismuth carbonate. Impurities in the bismuth subnitrate are not a factor in the poisoning because the metallic bismuth has been found in the local pigmented areas and in two well-defined cases the bismuth showed no impurities.—*Illinois Medical Journal.*

Medical Items.

Contagious Diseases, Weekly Statement.—Report of cases and deaths from contagious diseases reported to the Sanitary Bureau, Health Department, New York City, for the week of January 29, 1910:

	Cases	Deaths
Tuberculosis Pulmonalis	545	187
Diphtheria	447	48
Measles	896	15
Scarlet Fever	605	33
Smallpox	—	—
Varicella	256	—
Typhoid Fever	25	7
Whooping Cough	36	2
Cerebrospinal Meningitis	9	6
Malarial Fever	—	—
Totals	2,819	298

Recurring Vesical Calculi.—Pearce Gould reports the case of a man from whom in 1903 he removed an enlarged prostate and seven uric acid stones. In July, 1906, at a second suprapubic operation, a large, firm, uric acid stone with a coating of phosphates was removed. In January, 1907, and June, 1908, the patient was again under observation, but no stones were found. In October, 1909, however, for a third time, a cystostomy was done and a stone weighing 8 ounces was removed.—*Proceedings of the Royal Society of Medicine.*

Health Reports.—The following cases of and deaths from smallpox, yellow fever, cholera, and plague have been reported to the Surgeon-General, Public Health and Marine-Hospital Service, during the week ended January 28, 1910:

SIX CASES OF PNEUMONIA IN THE AGED, TREATED WITH PNEUMOCOCCUS VACCINE; RECOVERY.

By HENRY A. CRAIG, M.D.,

NEW YORK.

ASSISTANT PHYSICIAN, SAILORS' SNUG HARBOR HOSPITAL, NEW BRIGHTON.

THE following series of cases, though small, seems of some importance, on account of the age of the patients (66 to 83 years); the marked alcoholic history, several of the cases developing at the end of an alcoholic debauch; the poor general condition of the patients, all but one having chronic nephritis, and all showing marked arteriosclerosis; and the marked contrast between the results of the vaccine treatment, and the mortality from pneumonia here, in similar cases, previous to the treatment by vaccines.

Nearly all the inmates of this institution are over sixty years of age, and the mortality from pneumonia, for the past four years, previous to the present method of treatment, was 66 2/3 per cent. The cases have not been picked, but represent all the cases, diagnosed as lobar pneumonia, since the time the treatment was begun, in all of which the pneumococcus was isolated from the sputum, and vaccine made from the same.

The present plan of treatment is, as soon as the diagnosis is made, to give the patient a hypodermic injection of killed pneumococci, 20,000,000 to 35,000,000 in number, of a vaccine left over from the previous case of pneumonia, then making an autogenous vaccine from pneumococci isolated from his own sputum in our laboratory to carry on the treatment.

After determining the presence of an encapsulated diplococcus in the sputum, the same has been isolated by inoculating tubes of calcium-salt agar with washed sputum, pouring into Petri dishes, and incubating at 37° C., for 18 to 24 hours, at the end of which time, the tiny dew-drop-like colonies of pneumococci could be readily distinguished from the other colonies of bacteria, and inoculations made from the same into tubes of calcium-salt bouillon, and incubated again for 18 to 24 hours, at 37° C., when there would be obtained a suspension of large numbers of pneumococci in the bouillon, in pure culture.

The pneumococci were enumerated by making a number of smears on slides, of equal parts of the suspension of bacteria and blood, the cell content of which is known by previous enumeration (the operator using his own blood, as an index, in these cases). A drop of physiological salt solution is placed on a slide, a platinum wire loop full of blood added, then the same loop full of the suspension to be enumerated, is thoroughly mixed with the above, and a smear made, of varying thickness. The above method, in spite of the difference in the viscosity of the blood and bouillon, as compared with the method of Wright, using a pipette to obtain a definite mixture of blood and suspension of bacteria, was found to give practically the same results, and to be simpler and safer. The smears are fixed with methyl alcohol for five minutes, and stained with eosin and methylene azure (Giemsa). In a large number of microscopic fields, from the several slides, the average ratio of pneumococci to red blood cells was easily obtained and the number of pneumococci per cubic centimeter estimated.

The suspension of bacteria was then diluted with sufficient physiological saline solution to bring the number of pneumococci to 50,000,000 per cubic centimeter, sealed up in small glass tubes of one cubic centimeter each, and killed, by keeping in a hot-air sterilizer, at a temperature of 55° to 60° C., for three-quarters of an hour, and the vaccine was ready for use.

The inoculations of the killed bacteria, into the patient, were repeated in 24 to 48 hours, for one, two, or three doses, as found necessary; 20,000,000 being the minimum, 50,000,000 the maximum dose. In addition to the use of the vaccine, in these cases, the patients were treated symptomatically, being given stimulants, etc., when indicated.

CASE I.—Mr. S., age 83. Patient had just been on a prolonged spree and was on the verge of delirium tremens. The pneumonia started in with great severity. Patient had a chill soon after entrance into the hospital, temperature rose to 103.4°, respirations to 40 and pulse to 140, very irregular and intermittent. Albumin and hyaline casts in the urine. Rusty sputum, containing great numbers of pneumococci. Patient delirious. General condition bad, requiring stimulation from the first. The pneumonia started as a right central pneumonia, later consolidation of right middle and part of right lower lobes developed. The vaccine, consisting of 20,000,000 killed pneumococci, was given as soon as made, on the afternoon of the third day of the disease.

During the night the temperature dropped two degrees, and the general condition greatly improved, but the temperature rose again the next day. Second inoculation of 30,000,000 killed pneumococci was given 48 hours after the first. The next morning, the sixth day of the disease, the temperature was normal and lung beginning to clear. Out of bed, on the eighth day, lung practically clear. Discharged from the hospital eleven days after admission. Has remained well since.

CASE II.—Mr. R., age 75½. Alcoholic history. Two hours before entrance into the hospital, the patient had a severe chill. A sharp pain in right side and short, dry, hacking cough beginning soon after. Patient had been drinking heavily lately.

At time of entrance into the hospital, the patient had a temperature of 105°, pulse 124, respirations 40. Arteriosclerosis very marked. Heart considerably hypertrophied. Urine contained a heavy trace of albumin, and many hyaline and granular casts. Sputum rusty and contained great numbers of pneumococci. The pneumonia developed first in the right upper and middle lobes, with extensive dry pleurisy. The vaccine was first given on the third day, 20,000,000 killed pneumococci, prepared from his own sputum. The next day the temperature had dropped some and general condition had improved. Pain from the pleurisy was very severe. The entire right lung was solid except the anterior border. A second inoculation of 30,000,000 killed pneumococci was given 48 hours after the first, on the fifth day of the disease. The next day, the patient was very comfortable, temperature 99.2°, and general condition greatly improved. Consolidation of lung beginning to soften. Fluid present in right pleural cavity. The next day, the seventh, the temperature rose and the patient complained of pain in left side. Beginning consolidation of left lower lobe was found. He was given another inoculation of 50,000,000 killed pneumococci. The next day the general condition had improved slightly and the temperature had diminished a little. Left lower lobe completely consolidated. Fluid in right pleural cavity increased slowly, and several days later 800 cubic centimeters of thick purulent fluid was aspirated, containing large numbers of pneumococci that stained poorly, and cultures from the same remained sterile.

The lungs cleared rapidly, and the temperature was normal for the next ten days. Patient was up and about and very comfortable. Then he began to have an intermittent temperature and appeared septic. Fluid was found to be accumulating again in the right pleural cavity, and 300 c.c. of very thick creamy pus, containing the colon bacillus in pure culture, was obtained by aspiration. Vaccine was made. On each of the three following days an autogenous colon vaccine of 50,000,000, 100,000,000, and 150,000,000 killed cocci given, and two days a fourth inoculation of 250,000,000. This brought the temperature practically to normal, but the fluid in the pleural cavity caused considerable interference with the respiration and the heart action, and two days later, under hyoscine-morphine-cactin anesthesia, one inch of the eighth rib in the right postaxillary line was removed, 1,000 cubic centimeters of thick, creamy pus was allowed to drain out slowly, and a tube was inserted. The pus was negative as to bacterial content. The tube was left in two weeks, and one week later the incision was entirely closed, the pleural cavity free of fluid, and the patient entirely recovered.

Several weeks later the patient developed symptoms of an aneurysm of the aorta, which, a few days after the symptoms first appeared, ruptured into the esophagus, while the patient was sitting quietly on the veranda, causing instant death. At autopsy, there was found just external to the left innominate artery (the left common carotid and left subclavian arteries, came off from the aorta as a single branch, same as on the right side) a fusiform aneurysm, the size of a lemon, which had ruptured into the esophagus. The lungs were normal and right pleural cavity was clear, except for a few adhesions about the base.

Case III.—Mr. O., age 66. Patient feeble and in poor condition at the start. Had chronic nephritis, arteriosclerosis, and chronic endocarditis, with loud mitral systolic murmur. Action of heart rapid, irregular, and intermittent, compensation poor. Patient slightly cyanotic. Temperature varied between 101° and 104°. Required considerable stimulation during the course of the disease. Consolidation of entire right lung developed. The patient had no expectoration for several days, but later had typical rusty sputum, containing large numbers of pneumococci. Four days after entrance into the hospital he was given the first inoculation of vaccine, 50,000,000 killed pneumococci, repeated 48 hours afterward. The general condition of the patient greatly improved, but resolution of the lung was delayed, and convalescence was slow. The temperature did not reach normal till two weeks after entrance, and patient was not able to leave the hospital till a month later.

Case IV.—Mr. H., age 80. Patient emaciated and feeble. Arteries very sclerotic. Chronic interstitial nephritis present. Patient was in the hospital for several days, complaining of general pains and malaise, then had a chill, followed by a dry, hacking cough, pain in right side, and rusty sputum, containing large numbers of pneumococci. Total consolidation of right upper and middle lobes developed. Temperature kept about 103°, pulse 110, respirations 36. Patient was given a single inoculation of 50,000,000 killed pneumococci three days later, at which time the temperature was 102.6°. The temperature and pulse fell during the next 24 hours, and by the evening of the next day were normal. The lung cleared slowly, and the patient regained his previous condition, but is too senile and feeble to be discharged from the hospital, at this time (2½ months later).

Case V.—Mr. C., age 67. Patient was in good condition for a man of his years. Habits have always been good. Arteries fair. No nephritis. Came into hospital complaining of indefinite pains, of having taken cold, etc. The next day had a severe chill, followed by a temperature of 103.6°, pain in the left side, severe tight cough, with tenacious rusty sputum, containing large numbers of pneumococci. Leucocytosis of 41,000, polynuclears 87 per cent. Consolidation of lower lobe of left lung developed. The first inoculation, consisting of 50,000,000 killed pneumococci, was given the following day. The temperature fell a couple of degrees, but rose again the next day to 104.4°, respiration 36, pulse 104. Inoculation was then repeated with 25,000,000 killed pneumococci. Thirty-six hours later, the temperature was normal, and consolidation of lung beginning to soften. The patient was out of bed two days later, and discharged from hospital eleven days after entrance. He had no other medication than the vaccines during the whole course of the disease.

Case VI.—Mr. N., age 73. Patient in bad condition at time of entrance into the hospital. Had been on a spree for about a week, with severe exposure to wet and cold. Had been sick several days before entrance. The day before entrance into the hospital, had a severe chill, followed by pain in the left side of the chest, and a dry cough. Patient was very anemic, arteriosclerosis was marked, heart hypertrophied, action irregular and intermittent. Urine contained 1 per cent. albumin and great numbers of hyaline and granular casts. Temperature 103.4°, pulse 114, respiration 28. Leucocytosis of 45,000, polynuclears 92 per cent. The following day, he had developed a consolidation of the lower lobe of the right lung, and a small area in the left

axilla. He received an inoculation of 35,000,000 killed pneumococci. Within the next 24 hours the temperature dropped to 99°, but rose again. The general condition improved, except that patient was passing very little urine. A second inoculation of 25,000,000 killed pneumococci was given 48 hours after the first. Consolidation in the right lung was softening somewhat, but the process had extended in the left lung until it included the entire upper lobe. A third inoculation of 50,000,000 killed pneumococci was given 48 hours after the second, on the sixth day of the disease. The right lung was resolving, but the entire left lung was consolidated. The patient experienced some respiratory distress, from the amount of lung involved (respirations 40 to 46), but did not show much toxemia and required no stimulation during the whole course of the disease. The temperature dropped by lysis to nearly normal on the eighth day, but patient continued an irregular temperature, between 98.6° and 100°, for the next five days, until the left lung resolved. He then made a rapid convalescence, was out of bed 14 days after the beginning of the disease, and at the time of writing, is ready for discharge from the hospital.

HYPERCHLORHYDRIA.

By FENTON B. TURCK, M.D.,

CHICAGO, ILL.

Probably no condition of the stomach confronts a physician with such frequency as hyperchlorhydria. It requires more than mere examination of the gastric juice for the various acids to determine the etiological factors and the nature of the lesion present in the stomach. Many conditions pertaining in the upper part of the abdominal cavity have a similar symptom-complex, and to make a correct diagnosis necessitates more than physical examination.

On the basis of more exact methods I wish to discuss briefly the (1) Forms of hyperchlorhydria; (2) methods of examination; (3) treatment.

We find an increase in the HCl content of the gastric juice (*a*) in the early stages of gastritis; (*b*) in gastric neurosis; and usually (*c*) in cases of retention. Ulcer itself does not produce hyperchlorhydria. We may have ulcer of the stomach with no increase of hydrochloric acid, and also with no acid at all. But if ulcer interferes with the gastric functions, slight retention will occur, encouraging bacterial growth, which will be a factor in causing an increase in HCl. Furthermore, if a stomach is continuously acid and the ulcer-forming tendency exists, great irritation and pain will be pesent and the high acidity may not only prevent healing of an ulcer but may be contributory to its activity.

(*a*) In simple gastritis there is in the beginning an increase of HCl without retention; later on a decrease occurs. A bacteriological examination will show numerous colonies of bacteria growing in the empty stomach, especially on the walls.[1] If the patient lies down, material can be more easily obtained than in the sitting position. It will contain mucus, which is inhibitory to bacterial growth, and microscopic examination will reveal many epithelial cells, which on the contrary, are rich food for germs. The stomach seems to be a reservoir for the mouth waste, and desquamated cells are constantly being swallowed and also cast off from the gastric mucosa. On the surface of the mucous membrane bacterial colonies develop abundantly; no one kind of germ is characteristic of simple gastritis; rather a symbiosis occurs, and yeast in rich growth.[2]

(*b*) A neurotic individual frequently suffers with an acid stomach. But we cannot depend upon the mere symptoms of neurosis for a determination of the cause of the increase of hydrochloric acid. To ascertain the degree of functional hyperchlorhydria, two factors must be ruled out: (1) The psychic influence of the food itself and its mastication; and (2) the influence of abnormal food stimulants, especially of the extractives of meat. The patient should be fed for several days through a small stomach tube, with food of the simplest character—eggs, milk, ground toast made into gruel, and extract-free meat.[3] If the acidity keeps down as the result of tube feeding, then the condition is one of neurosis and can usually be handled by regulating diet and habits of the patient.

Severe mental strain, especially soon after eating; too little exercise, fresh air, and sunshine; smoking, and an unhygienic diet are prominent causes of gastric neuroses. Students, lawyers, bookkeepers, and stenographers would do better to omit luncheon. To rush out for an hour at noon, partake hurriedly even of simple food, and then return immediately to mental activity work disaster to brain and stomach. Both cannot simultaneously work hard; the one robs the other of blood, and either the brain becomes confused or the food undigested. The noonday meal is usually injurious to brain workers and may cause continual distress. The farmer and outdoor laborer can overeat with less disaster than the mentally taxed individual.

If gastric neurosis is not relieved by removing the various causes, permanent lesions of the stomach will follow—chronic gastritis, ulcer, dilatation, and ulcer developing into cancer. The liver, pancreas, and duodenum may also suffer. Such individuals need a simple, non-stimulating, nutritive diet, but we usually find the food in these cases to be of the most stimulating variety—condiments, highly seasoned meats, rich pastry, together with alcohol and tobacco. By experiment we have found that the extractives of meat not only possess no nutritive value, but are locally irritating to the stomach and may act as poisons. They form a rich medium for the growth of microorganisms and by their continual use the stomach and intestines become an excellent culture chamber.

The accompanying charts are a graphic illustration of the difference in acidity of the gastric contents with an ordinary meat diet, and with a diet of meat freed from extractives in a case of severe hyperchlorhydria.

The two following cases are illustrative of hyperchlorhydria of the neurotic type:

Case I.—Mrs. B., aged 63 years, wife of farmer. Patient appeared calm and composed, and took the stomach tube with ease. Complained of fluttering in region of stomach, had difficulty in swallowing food, and "heart burn." Analysis of gastric contents showed very high free HCl and total acidity. No retention present and stomach was normal in size. Patient was first fasted two days to give stomach rest and to rule out any retention. Then for one week a mixture of eggs, milk, and starch was given by tube. Second week patient had gastric tube feeding in morning and mouth feeding at night. The colon was thoroughly lavaged two or three times a week to remove excess of poisons. The diet was regulated—simple food consisting of rice and milk, extract-free meat, baked apples, toast, etc. In three

weeks the cardiac spasm had disappeared and the acidity was normal. In this case the cause seemed to be due to severe strain of domestic life. Many farmers' wives are overtaxed with the care of house and children, take very little rest, and eat a hearty meal of coarse food when tired. This may account for so much psychosis in rural districts.

Case II.—Mr. K., aged 52 years, peddler. Patient was nervous, easily upset, weighed 200 lbs., heavy smoker and overeater. Stomach was dilated, contents highly acid, and continuously so. Blood clots were present in stomach contents. Colon dilated, diarrhea at times with severe cramping. Blood pressure 170. Patient yellow. Stomach was washed out with nitrate of silver 1-1000. Soap and ox-gall mixture relieved bowels. Diet of extract-free meat, rice, toast, and stewed fruits twice a day given. Stomach still showed continuous acidity. Smoking was then prohibited and patient was given tube feeding for ten days. Quick response—coating left tongue and gastric acidity became normal. At present is in good condition except when he smokes.

(*c*) The hyperchlorhydria of retention is most common of the three forms. Retention may be present in the neurotic type and yet be the result, and not the cause, of the high acidity. The diagnosis of the retention form is easily determined. Witdraw all food from the stomach and examine it in the fasting state. The acidity will disappear when the food does. Even microscopic food remnants are a cause of irritation and will keep up a constantly high acidity so long as present in the stomach.

The retention may be due to stenosis or atony. The behavior of the gastric muscle in expelling air from an inflated stomach differentiates between motor insufficiency due to obstruction, and that due to fatigue of muscle. The force with which air is ejected from the stomach tube can be felt with the hand or cheek, and gives some idea of the tonicity of the muscle. In stenosis the muscle wall hypertrophies to compensate for the increased resistance of the pyloric outlet and will require greater degree of tension than normal to distend it. The air coming from such a stomach will escape promptly with energetic puffs.

On the other hand, in gastric myasthenia the muscle becomes less and less resistant to tension and air leaves the stomach in a slow stream, with little force. If nebulized oil be used, the escaping cloud is faint and diffuse.

The following case is illustrative of the retention type of hyperchlorhydria:

Case III.—Mr. P—, aged 22, case of retention due to gastric myasthenia. Patient had been sick about six months before coming to clinic. Stomach was dilated, lower border extending to symphysis pubis. The whole conformation of the trunk was of the congenital type and general enteroptosis existed. Stomach was examined with patient in sitting posture, over period of several days, and no retention observed. Patient was placed in reclining position and examination was made for presence of food in stomach. With very slight air pressure, the contents were easily obtained. If food remnants were present, even though microscopical, the hyperacidity kept up; if no food was present; there was no acidity. This case was one of retention with atony of the muscle. If the stomach were inflated with air, the return was slow and with very little force. Patient was given most careful course of treatment for stomach. Tube feeding for ten days of non-stimulating food indicates neurosis to be also a factor, as the acidity and retention decreased. For four weeks the stomach was exercised with water at 120° F. in the intragastric bag before evening meal. Patient at same time wore abdominal supporter to increase intraabdominal pressure. Fruit diet for eight days was given, and then followed by diet of toasted flakes, stewed fruits, extract-free meat, rice, and milk. This treatment reduced the acidity, and the retention was relieved. Patient was sent to camp life. In three weeks' time, the motility of the stomach showed marked improvement and the acidity kept normal. Five weeks later, patient returned for a little general treatment because of catching cold. He was under observation for one week, and stomach was examined twice daily. No retention or hyperacidity were found.

In all cases of retention with hyperchlorhydria I give the patient but two meals a day, and at first, possibly, only one. Myasthenia seems to be more common than stenosis, and the stomach cannot do effectual work if three meals are given. I daily examine the stomach for the presence of food from five to eight hours after eating.

Methods of Examination.—The examination of the stomach with a rubber tube is usually dreaded by the patient, and the nervous fear entertained may prevent the introduction of the tube into the stomach. Where such a condition exists, I use my intragastric reagent capsule for determining the presence or absence of gastric acids. This I first described in the *British Medical Journal,* Nov. 19, 1898. This summer (1909) I found it in use in the clinics of Europe. The reagent capsule contains a small piece of rubber drainage tube about an inch in length, slit so as to carry three test-papers or bits of cloth, colored with litmus, Congo red, and dimethyl-amido-azobenzol. The small tube with the inserted papers or cloth is placed in an ordinary gelatin capsule, which can be readily swallowed by the patient. Through the tube is passed a silk thread carrying a good-sized lead shot at the end. In five minutes the capsule will dissolve in the stomach; the rubber tube fills with gastric juice and the test papers or cotton become saturated. When the string is withdrawn fifteen minutes after swallowing, the coloring of the papers will at once indicate the chemical nature of the stomach contents. The liquid in the little tube can be used for further examination.

The reagent capsule causes the patient no distress and it gives a qualitative test for acidity of the stomach contents. This aids materially in making superficial examination of a sensitive patient, who will later more easily submit to the use of the stomach tube.

I prefer to examine the stomach with the patient in the reclining position. The stomach contents then flow out of the tube with ease; and in cases of prolapsed stomach, the lowest part of the cavity where the food or secretion is more easily reached. Care should be taken that the tube is sufficiently long. I recently had a case giving all the symptoms of hyperchlorhydria of retention, and yet several examinations of the stomach, even with the patient in the reclining position, had revealed (one hour after test meal, and also four to five hours after regular breakfast) small amount of food remnants, mucus in abundance, and no free HCl. I made another examination (four hours after regular breakfast) with a very long double tube, introducing it full length. I then inflated the stomach with air under gentle pressure, until the outline of the greater and lesser curvatures could be seen on the surface. Almost

immediately the food began to come from the tube. Pressure of the hands upon the abdomen caused it to literally pour out, the gastric muscle being so weak that almost no peristalsis was present, and the outflow was dependent upon the pressure of air within and of the hands without. In this instance I obtained nearly a quart of highly acid food, which soon separated into granular and fluid layers. Further examinations confirmed my diagnosis of hyperchlorhydria of retention due to atony.

The expulsion method of obtaining gastric contents excites peristalsis, which is the important factor in expelling the food through the tube. This frequently takes place, even though the tube used is too short to reach the lower part of the stomach where the food and secretions lie. If the stomach is dilated and the muscle is atonic, as in the case just cited, the tube must be long enough to extend into the contents.

The nature of the response of gastric muscle to compressed air inflating a stomach indicates definite conditions. From a dilated myasthenic stomach, air will return slowly and with little force. If nebulized oil is introduced into such a stomach, the cloud escaping at the end of the tube will be faint and diffuse. The opposite results are obtained from a "leather bottle" stomach or one in which the muscle is hypertrophied because of pyloric stenosis. If compressed air be injected, it will return almost instantly, as from a bottle, in short, sudden puffs, which can be distinctly felt with the hand or cheeks. The volume and pressure of air which a stomach will hold without pain or cramping indicate the size of the organ. With the patient in reclining position, the outline of the curvature can easily be made by inflating with air. As the air enters it has a peculiar rumbling sound, and the force of it can be felt through the abdominal wall. This obviates the confusion which often arises from mistaking a dilated colon for stomach.

The double stomach tube would appear to be much the best for gastric examination and treatment. By this means air can be introduced through the small tube, while the larger one permits an immediate escape of the air in response to peristalsis. The distress to the patient is less than in the use of single tubes, and the danger much less. It is not necessary here to consider conditions in which the stomach tube should not be used.

For gastric lavage I prefer the patient to lie down. The water is in this position more easily syphoned out, and by placing the patient on his side, with the head over a portable sink or large basin, the floor and adjacent furniture do not become soiled with suddenly expelled contents from the stomach. Furthermore, it is especially advantageous to administer gastric lavage to a patient in the reclining position.

Methods of Treatment.—In all cases of hyperchlorhydria, as far as possible the cause should be removed. Usually more than one cause exists, and it is frequently difficult to persuade the patient to give up habits which are either very dear to him or else very necessary to his livelihood. Consequently, the treatment of these cases may entail a complete change in life and work.

I shall consider briefly the following details: (1) Habits of living; (2) Diet; (3) Medicine; (4) Local applications to the stomach; (5) Local applications to the colon; (6) Surgery.

(1) Habits.—In many cases of hyperchlorhydria, especially of the neurotic type, if the causes are removed, the patient will soon recover. Outdoor exercises, fresh air, and sunshine should break up the monotony of sedentary life. The devitalized air of a building robs the skin and internal organs of their tonicity, and the reflex areas lose their sensitiveness. Coffee and tea result in similar conditions. The first effect of coffee is exhilarating. Many, therefore, think tea and coffee do them great good; but their effect is produced before digestion or assimilation have taken place, and what seems to be strength is only nervous excitement. The overworked nerves and muscles of the stomach need rest and quiet, instead of abnormal stimulation.

Tobacco and alcohol should be discarded. Tobacco is a slow, insidious, malignant poison, and, in whatever form it is used, it is irritatng to the stomach. It is all the more dangerous because its effects are slow; but once the stomach has succumbed to it, and the muscle is weak and atonic, an immediate effect follows every dose of tobacco.

(2) Diet.—Highly seasoned foods, hot sauces, mustard, pepper, spices, pickles, and the extractives of meat are frequently responsible for hyperchlorhydria. If a patient has partaken freely of these kinds of food, he should change to a more simple diet. The extractives of meat not only possess no nutritive value, but are irritating to the stomach. They also increase the growth of bacteria. The fat in beef is largely stearin, and it taxes a weak digestion more than do fats with a lower melting point, such as cream. If meat is prepared free from the fat and extractives, its nutritive value is not lost, but really increased, on account of the protein concentration. Soak chopped or ground steak in ice water for twenty-four hours; press out juice, and wash pulp in boiling water to remove fat; steam in autoclave or steamer, if possible, under 20 to 30 pounds pressure, for four to five hours. Drain the meat stock of its water and keep on ice. By this method, not only are the irritating elements of the meat discarded, but it is rendered more digestible; the high temperature hydrolyzes the connective tissue into gelatin. This stock can be made up into creamed meat, meat loaf, stuffed tomatoes, etc., the flavors being supplied in the form of mushrooms, celery, and onion, while cream and butter substitute the discarded fat. This process also renders the meat salt free, which in some cases is an advantage, as I order all food to be taken for a time free from salt, in advanced hydrochlorhydria.

Rapid eating and overeating are frequent causes of hyperchlorhydria. To break up these habits, let dry, hard toast or biscuits be a part of every meal. On the other hand, caution should be taken that the patient does not chew his food too long, lest the psychic influence of this extreme increase the already existing secretions. Steamed rice, stewed berries, especially huckleberries, baked apple, creamed toast, poachd egg on toast, puree of pea, cream pea soup, and extract-free meat make a representative dietary. Let the meal consist of two or three kinds of food only. Some patients cannot take more than one kind, at least for a long time. Frequent meals increase both psychic and reflex secretion. A longer pause or rest period between meals often produces brilliant results. Two meals a day, breakfast at seven or eight o'clock, and dinner at five or six o'clock in the evening, are an important prescription. Oftentimes this regulation alone puts the patient on his feet. The rest thus given the stomach may enable it to heal without other treatment. Aside from the diet regulations, I make out a few rules of hygiene for my patients:

1. Plenty of fresh air every day; if possible, sleep in open air.

2. Do not drink with meals. Drink freely of water in middle of day, beginning three or four hours after eating.

3. Avoid such combinations as milk and sugar, fruit and vegetables. Do not take bouillons or meat broths. In general, leave soups out of the diet.

4. Plan to eat two or three substantial foods at a meal. Fruits and cereals can be best eaten in the morning; vegetables and meat at dinner.

5. From eight to ten hours should intervene between breakfast and dinner (time in each case determined by examination).

6. Do not eat when tired; be cheerful at meal time; do not eat alone. Take plenty of time for eating; chew the food thoroughly, but not too long. Never eat between meals, not even sweets and dainties.

7. Avoid sweet desserts and rich salads.

8. Discard tobacco and alcohol, tea and coffee.

Gelatin and agar-agar are very soothing to irritated stomachs. Gelatin makes up best as a simple dessert; agar-agar, as a breakfast food. Agar-agar prohibits germ growth; it helps to lessen the bacterial infection so often present in the stomach in hyperchlorhydria, and it breaks up the infections in the colon and, therefore, relieves the constipation frequently accompanying this condition.

(3) Medicinal Treatment.—The use of carbonic oxide gas lessens the irritable sensations in hyperchlorhydria, and it is customary for patients to drink aerated waters. The gas stimulates peristalsis by the stretching or tension produced upon the muscle wall. The relief obtained by taking bicarbonate of sodium is due not only to the resultant neutralization of the acids, but the nascent carbonic acid gas also mechanically stimulates peristalsis. Peroxide of hydrogen (one to two drams in water) lessens distress in the stomach by inhibiting bacterial growth and by checking the over-production of acid. It is, therefore, a most valuable gastric remedy and is harmless. The more recent oxidizing remedies that liberate oxygen slowly possess the advantage of not being so fulminating in effect.

While alkalies usually bring relief, indiscriminate use of them may increase the irritability. Magnesia has more combining power than bicarbonate sodium, and is less irritable. Mixed alkaline treatment is most efficacious. The following prescription has proven of considerable value:

Mentholis ..... gr. ii
Sodii bicarb ..... ℥ ii
Potassii bicarb ..... ℥ ii
Magnesii carb .....
Calcii carb ..... a a ℥ ss
Bismuthi subnitratis ..... ℥ ii
Triturate Sig. Take a pinch every hour or a teaspoonful three or four times a day.

Case of Duodenal Ulcer with Hyperchlorhydria (retention type).— Stomach dilated and prolapsed; mucous colitis; obstinate constipation; intestinal glycosuria. Series of gastric examinations here recorded followed course of treatment for ulcer. June 27 consultation held, operation advised which patient refused and requested further treatment. From June 21 – Sept. 12 Stomach was tested twice daily for acidity, before breakfast and before dinner. In morning colon was lavaged; in afternoon indirect lavage (water at 50°C) was given stomach in intragastric bag. Hot and cold compress applied over stomach after each meal. Patient sent to camp Aug 6, returning each week for colonic lavage and stomach treatment. Oct 1 had gained 12 lbs., stomach still improving, with normal acidity after test meal

In gall-duct and hepatic disturbances associated with hyperchlorhydria, soap combined with ox-gall may be given in capsules. The salicylates will excite hepatic function; they are also useful in hyperchlorhydria associated with lithemia, acid rheumatism, and gouty conditions. Urotropin in 10 to 20 grain doses has a sterilizing effect of considerable value.

Olive oil possesses the advantage of not stimulating further production of HCl and would seem to be a useful remedy as a local protection to the gastric mucosa. But in cases of retention, the olive oil undergoes decomposition, setting free fatty acids and thus increasing acid irritation. Vaseline, on

the other hand, seems to offer soothing protection to the stomach, and it does not decompose. It inhibits bacterial growth and frequently relieves constipation.

No systemic drug treatment for hyperchlorhydria and its associated conditions can be compared with the hypodermic injection of atropine, followed later by physostigmine. Atropine has a quieting antispasmodic effect, yet does not check peristalsis. It also renders the mucosa less sensitive to local irritation causing spasm.

Physostigmine produces favorable conditions for peristaltic movement induced by the stomach or intestinal contents. Inject daily 1/200 to 1/60 gr. of atropine sulphate and follow later by 1/60 to 1/20 gr. of physostigmine sulphate. Begin with the minimum dosage and slowly increase. This will through muscle and glands, with a resultant stimulation of new antibodies. In this procedure some albuminate of silver is formed and carried down into the duodenum, causing an intense hyperemia of the mural structures. The common duct is closed and the liver and pancreas swell up, the liver sometimes nearly an inch in diametric increase. In three to twelve hours reaction takes place, the duct opens wider, and the retained secretions flow out in abundance. Their alkaline reaction influences the pylorus so that the stomach can empty itself: the acid contents of the bowels are neutralized, and intestinal digestion is assisted; constipation is relieved; the stool may even be loose for a time. One or two applications of the silver nitrate lavage may start the patient permanently in the right direction; it should not be repeated oftener than every other

accomplish most excellent results. The injections may be made intramuscularly in the gluteal or crural regions.

(4) Local Applications to Stomach.—A stomach which has been highly and continuously acid for some time needs local treatment. To neutralize the excess of acids either by combining them with albumen, or by the administration of alkalies, does not reduce the hyperacidity permanently, and may increase it. Applications affecting the circulation of the stomach are more effectual. Gastric lavage with silver nitrate 1/1000 is very helpful in cases of high acidity due to gastritis, cholangitis, and disturbances of the liver with secondary stomach symptoms. The first effect of the silver nitrate upon the stomach is a superficial coagulation of the cells; the dead epithelium, débris, and mucus are washed away with the lavage water. An intense hyperemia then follows, some blood may even color the washings, but the end result is a normal circulation of the stomach. The venous congestion is broken up and fresh arterial blood and lymph course day, and should always be given to a fasting stomach, never when food is present. Soap lavage is also useful in hyperchlorhydria, especially when due to hepatic infection. Soap not only mechanically cleanses the stomach, but it is found to be one of the most powerful excitants of secretin, which enters the circulation and stimulates the glands. Their fresh secretions hinder the growth of microorganisms. By adding oil of cloves, oil of cinnamon, and menthol, the douching solution may be rendered still further antiseptic. Slippery elm also makes a soothing lavage.

On account of the tendency of lavage to increase atony of the stomach, its use is limited. It is my custom to begin the course of treatment with one or two applications of lavage, and then proceed along other lines.

If the hyperchlorhydria is due to atony of the muscle and retention, it can be relieved by improving the motility. Exercising the stomach with air results in local stimulation of the muscle wall. Compressed air may be introduced directly into the stom-

ach through a short double tube, and intermittent distention applied. If the air is first passed through a solution of hot water (60° to 65° C.) to which has been added a few drops of a mixture of oil of cloves and 15 per cent. menthol, the heated moist air impregnated with an antiseptic analgesic stimulant makes the gymnastics of the muscle more efficacious. A pressure of 30 to 40 mm. of mercury can be used without causing distress and without any harmful results. If the treatment is given before the evening meal, it at once improves the appetite, initiates peristalsis, and the stomach begins to empty itself more quickly. A patient soon finds the treatment agreeable, the pleasant sensation of which overcomes the momentary dislike of the stomach tube. It is frequently advantageous to substitute cold dry air for heated moist air, or the two may be alternated to increase stimulation. A spray of nebulized oil may also be used as an alternative. The physiological effect of this treatment increases peristalsis, and favorably influences not only the gastric but all the splanchnic vessels.

When the gastric muscle is extremely weak and relaxed, pneumatic gymnastics cannot be used, and even direct lavage of the stomach may be disastrous. In such cases the gastric muscle may be stimulated by alternate applications of hot and cold water in a rubber bag (indirect lavage). A thin rubber bag is carefully tied to the end of a long single stomach tube and introduced into the stomach. The thin rubber does not enlarge the tube materially. Water at a temperature of 50° C. is allowed to run into the bag until the patient feels the pressure. At the end of two or three minutes the water is returned and a new supply introduced. After four or five applications of the hot water, a short cold douche is given for retoning the stomach wall. By this treatment we obtain a high degree of passive exercise to the gastric muscle, with a minimum amount of fatigue on the part of the patient. We do not rob the stomach of any of its secretions, and if acids are present, they often are neutralized by the treatment.

(5) Local Applications to the Colon.—The colon is with frequency disturbed in patients suffering from hyperchlorhydria. The cause may be located there, and an intestinal infection responsible for the lowered resistance of not only the stomach, but of the whole body. It is, therefore, advisable to carefully examine the colon and stool in cases of stomach distress. I have even placed the stomach on a good working basis by treating the colon alone. More frequently than not, constipation and retention, mucous colitis, dilation of the colon, and diarrhea are coexistent with the hyperacidity of the stomach and may be the result of it. Daily lavage of the colon with water at 50° C. for a period of two to six weeks may relieve the retention of the bowel. If the muscle is weak, the hot water will increase peristalsis; if spastic conditions are present, the water should be applied at lower temperature.

(6) Surgery.—Surgical procedures in cases of hyperchlorhydria should be limited to absolute mechanical obstructions. This conclusion has now been reached by the most experienced surgeons. Cannon has recently shown that no alteration in peristalsis occurs when a new opening is made into the stomach, the food continuing to pass through the normal opening as usual.[4] The supposed rest to a selected portion of the stomach does not take place. When stenosis exists, according to Cannon, the passage of food through a new opening does not allow proper admixture with bile and pancreatic juice. Fat and protein may therefore pass through the alimentary tract without being absorbed.

The long-used methods of treating hyperchlorhydria and its associated conditions have not been successful; they are based on histopathology and anatomical structure, depending upon some ocular demonstrable lesion for application. The new pathology of digestive diseases concerns functional disturbance and motility. It offers entirely new foundations for treatment and changes the whole aspect of the cause and effect of these conditions.

THE ROLE OF CEREBRAL LESIONS IN INFANCY AND CHILDHOOD IN THE CAUSATION OF EPILEPSY.*

By M. L. PERRY, M.D.,

PARSONS, KANS.

SUPERINTENDENT STATE HOSPITAL FOR EPILEPTICS.

Injury to the brain is one of the well-recognized causes of epilepsy, and the brain injuries of infancy and childhood resulting in paralysis are discussed more or less at length by all writers upon the etiology of this disease. All agree that a large number of patients afflicted with infantile cerebral palsy sooner or later develop epilepsy, and this condition is given as a direct cause of this disease by different authors in from five to ten per cent. of cases. While the relation between these two diseases has been repeatedly pointed out, a study of a large number of epileptics has led me to believe that the importance of brain lesions in infancy and childhood in this connection has not been given sufficient emphasis. I am quite convinced that the profession in general does not fully appreciate the intimate relation existing between the two conditions, nor the importance of the one as an etiological factor in the production of the other.

Infantile cerebral palsies are usually divided into three groups: First, those in which the lesion occurs *in utero*; second, those sustaining injury at the time of delivery; and third, those developing paralysis after birth. The first of these groups is a relatively unimportant one, as cases of this kind are not of very frequent occurrence. A considerable number of cases fall into the second group. Most of this type occur in long tedious labors and often in the delivery of primiparæ. The injury sustained is usually a meningeal hemorrhage, but may be an actual laceration of brain tissue by pressure of forceps. The symptoms are usually so evident and profound that the serious nature of the case is recognized at once. The possibility of such a lesion

*Read before the National Association for the Study of Epilepsy and the Care and Treatment of Epileptics at the eighth annual meeting at Indianapolis, Ind., November 11, 1908.

occurring and the consequences from it should be borne in mind in all cases of protracted labor and instrumental delivery. The practice of too frequent, and at times uncalled for, use of forceps by unskilled obstetricians is undoubtedly to blame for a certain number of the palsies of this type. The third group is by far the most important of the three, the number of cases of this kind being greatly in excess of the others. There is considerable difference of opinion as to the exact pathology in these cases owing to the fact that it is unusual for a case of this kind to come to autopsy during the acute stage, and the changes found in chronic cases are indefinite and often confusing. Strumpel in 1884 first advanced the idea of an inflammatory origin of the disease, the paralysis resulting from an injury or destruction of cortical cells similar to that found in the cord in anterior poliomyelitis. This theory of polioencephalitis had a wide acceptance, and appears to be still supported by the majority of German writers. There has recently been a tendency on the part of some neurologists in this country to return to this theory, but it is safe to say that the prevailing opinion among American and English authorities is that the lesion in this disease is more often a vascular one. Here again authorities hold different views as to the exact pathological process, some adhering to the idea of embolism and thrombosis, and others to a hemorrhagic lesion. Gowers, who supports the first of these views, in discussing the subject, says of the theory of polioencephalitis: "Attractive as the latter theory is at first sight, it rests upon no evidence, and * * * the scanty pathological facts we possess are opposed to its validity as are also the facts of etiology." Further on in the same discussion he says: "The alternative theory, vascular obstruction, has much to support it. It is the common cause of such central cavities as have been found in some cases. It is a known consequence of such general diseases as frequently precede the cerebral lesions. It has been found in some cases of the kind. A cavity in the central ganglia can hardly be due to any other cause than arterial obstruction." Dana says: "The causes are those which lead to intracranial hemorrhages, embolism, and thrombosis." Church is of the opinion that hemorrhages occur more frequently than thromboses. Sachs, who has given a great deal of attention to such cases, and has been one of the most pronounced advocates of the theory of vascular lesion, says in his text on "Nervous Diseases of Children": "The writer has departed from his former views to the extent of conceding that a small number of the acute cerebral palsies of children may be due to an hemorrhagic (infectious?) encephalitis." In the same work the further statement is made: "The truth is that encephalitis is the rarest cause of these palsies and should not be considered at all unless every other morbid state can be safely excluded." My own opinion, based upon a considerable clinical experience and some pathological work in these cases, is that the primary pathological process in the greater number of instances is a vascular lesion. I have observed many cases with histories of a mode of onset and course irreconcilable with the idea of an inflammatory process. The fact that the disease is always sporadic and is but seldom found as a complication in epidemics of acute polimoyelitis, as well as the different anatomical changes found in the cerebral an l cord palsies, indicates a different pathology for the two conditions. Diffuse sclerosis with atropy, indicating a probable inflammatory origin, is found, it is true, in a considerable number of palsies of the cerebral type, but porencephalus, cavities, cyst formation, hemorrhages, and such vascular lesions are the predominating anatomical changes found. There are undoubtedly a number of different morbid conditions that underlie and account for the actual lesion in cases of vascular origin. In those cases developing in the course of one of the acute infectious diseases, the process is most probably one of embolism or thrombosis due to alterations in the blood state and the circulatory system. The fact that it develops late in the course of the primary affection would indicate such a process. Some morbid changes in the vessel walls appear to be present in some cases, especially in those of an hemorrhagic type. Infantile convulsions are, I am convinced, a much more important factor in this connection than is generally supposed. Among the authorities, Sachs and Osler have been notable adherents to this idea, and Jacobi, in an article on "Causes of Epilepsy in the Young," makes the statement: "Every convulsion ever so slight or short may produce cerebral hemorrhage with all its possible results, epilepsy, idiocy, paralysis, and insanity." I have observed a number of cases of young children previously healthy who, after the ingestion of quantities of irritating and indigestible food, were attacked with convulsions, accompanied by profound depression, and followed by a partial hemiplegia, and later on became epileptic. In these cases, from a purely clinical standpoint, the convulsions have every appearance of standing in a causal relation to the brain lesions, probably hemorrhagic, which in turn were the cause of the epilepsy. Granting that such well-defined cases are rather unusual, the fact that they do occur is sufficient grounds for the position that the so-called simple convulsions of infancy and childhood should be considered in a much graver light than they are usually regarded by the general practitioner. In view of the fact that infantile convulsions may, even occasionally, be followed by such dire results, it is certainly the duty of every physician to recognize this possibility and take due precaution to prevent their occurrence.

The same type of lesion, whatever may be its cause, which produces the well-known clinical entity of infantile cerebral palsy when it happens to strike the motor centers, is liable to fall in some other part of the brain. Freud, I believe, first called attention to such cases, referring to them in the paradoxical but apt phrase of infantile palsy without palsy. Most writers upon nervous diseases discuss this condition at some length, but I believe the subject has not been given the attention which it deserves. When the lesion is located so as to impair or destroy the center for some special sense or function, as vision or speech, it is, of course, recognized, but when it falls in some part of the brain not giving localized symptoms, the so-called silent areas, it is only discovered on the autopsy table, if at all. The lesions, in fact, are often small, and after years have passed may become more or less healed, leaving only small scars that may escape the attention of the pathologist. It is surprising to note the serious results sometimes following very small destructive lesions in parts of the brain not usually supposed to be so exceedingly vital. I recall a case of a man suddenly seized with a convulsion involving one side especially, who died in less than half an hour without regaining consciousness. I made a

careful postmortem examination of the patient and found nothing to account for his sudden attack and death except a few small hemorrhages, none larger than a pea, in the posterolateral portion of the optic thalamus. The lesion was on the opposite side from the more pronounced convulsive movements. Every pathologist will bear witness to the comparative frequence with which destructive lesions in the brain are found upon section in cases where they have not been suspected. This is especially true of patients suffering from epilepsy and is, to say the least, a very suggestive circumstance. In this connection it is quite interesting to quote from Dr. Neu, pathologist of the Central Indiana State Hospital for the Insane, in his discussion of a case of brain tumor reported in a volume recently issued by the pathological department of his hospital. He says: "The case also is illustrative of a group whose clinical manifestations are very similar to, and not always differentiable from, those constituting the symptom complex of true idiopathic epilepsy. In the latter no visible, macroscopical alterations are found. In the former, there is present some pathological condition, such as tumor, a hemorrhage, an area of softening, an inflammatory condition, vascular disease, or other conditions as a direct exciting cause. It does seem that there should be some means whereby an epileptoid symptom complex could be differentiated from a true idiopathic epilepsy. At present, however, we must confess to an inability to do so, since on the one hand one often meets with cases which during life are regarded as idiopathic epilepsy and the autopsy reveals the presence of some gross organic lesion, while, on the other hand, one also meets with cases regarded as epileptoid, due to some gross lesion and are operated upon as such, but operation and autopsy fail to discover the existence of any visible gross lesion."

The question naturally arises, it is not very probable that in such cases there is a real lesion, small in itself, or possibly healed and leaving only a scar which has escaped both operator and pathologist.

Gowers, in discussing infantile convulsions as forerunners, not necessarily causes *per se* of epilepsy, gives three characteristic features to that form of epilepsy resulting from an organic disease of the brain during infancy. They are; first, the epileptic convulsions are more or less one sided; second, the first attack of infantile convulsions was of great severity; and third, that the first convulsions often occur during some acute illness, or soon after a fall, or in a state of general physical prostration. How familiar to those of us seeing large numbers of epileptics, is the picture, more or less definite and exact, of this clinical history! All observers must have been impressed with the number of epileptics whose seizures show regularly a more or less pronounced one-sided element. It is found in thirty-five per cent. of the four hundred epileptics in the Parsons State Hospital. A careful and thorough physical examination will not infrequently reveal one-sided symptoms or phenomena in patients showing no evidence of them to a casual observer. It may be only a heightened reflex with evidence of a slight unilateral retardation in development as found by actual measurement, or a tendency to abnormal laxity in the articulations of a member, or a more rapid tiring and exhaustion of one side after continued exertion, which when found are indicative of a cerebral lesion as the origin of the disease. A careful inquiry into the history of epileptics will disclose the fact that quite a number of them suffered at some time during infancy or childhood from attacks of convulsions characterized by an unusual amount of constitutional depression, and involving one side more than the other. It is maintained by some good authorities that most, if not all, cases of epilepsy dating from an attack of some acute infectious disease, as measles or scarlet fever, have as their pathological basis a cerebral lesion.

From a study of the subject, both from a clinical standpoint and a consideration of pathological findings, I am of the opinion that cerebral lesions in infancy and childhood have a much more important influence in the development of epilepsy than is usually attributed to the condition, and that the importance of such cerebral lesions as a causal factor is second only to bad heredity.

A CASE OF NOMA FOLLOWED BY CICATRICIAL CONTRACTION OF THE JAWS.*

By WILLIAM C. LUSK, M.D.,
NEW YORK,
ASSISTANT VISITING SURGEON TO ST. VINCENT'S HOSPITAL.

The patient, a girl aged 4 years, was admitted to Bellevue Hospital June 27, 1903. She had been caught under a horse-car and had three-quarters of the skin torn from the right leg. The wound was treated with continuous irrigation of bichloride of mercury, 1-20,000, until July 9, when symptoms of mercurial poisoning developed. On July 12 there developed double gangrenous stomatitis and antitoxin was given. Cultures from the mouth showed streptococcus, staphylococcus, and diplococcus. The lesions were at first treated with irrigations of saline, Dobell's solution, and a weak peroxide. The process on the left side, which was the side on which the patient lay, was cured. On the right side the hardening diminished for the first week and then the disease advanced again. By July 23 the skin over the induration had thinned. On July 25 the cheek perforated. The hemoglobin was 55 per cent. *Operation* was performed on July 26. The noma was excised peripheral to the induration, and the cut surface treated with pure carbolic, followed in two or three minutes by alcohol. The circumscribing incision reached above to the malar bone and posteriorly to a little behind the anterior border of the masseter muscle. The angle of the mouth was saved. The tip of Stenson's duct was necrotic. The upper jaw presented an area of necrosis. A piece of the indurated tissue, deeper than the slough, was planted by Dr. J. E. Welsh in a rabbit's mouth. The animal developed a gangrenous stomatitis on the following day, and on the next day died. *Result:* The extension of the process in the patient was completely arrested by the operation. Cicatricial contraction of the jaws supervened.

The first plastic operation was done on February 20, 1904. A flap was taken from the neck (Israel's operation) and, in accordance with the technique of Dr. B. Farquhar Curtis, was slipped beneath a bridge of skin raised from the lower jaw below the defect, through an incision just beneath the lower margin of the jaw. The skin side of the flap was turned toward the mouth. The flap, one and one-half inches wide, its base situated in an oblique line downward and forward from a point half an inch below the angle of the jaw, was cut downward and

*Patient presented at a meeting of the Surgical Section of the New York Academy of Medicine, January 7, 1910.

outward along the side of the neck to a point three-quarters of an inch below the clavicle. All of the scar tissue was removed from the defect except that behind the angle of the mouth, which was cut free above and below from its sites of attachment to the jaws. Stenson's duct, which was caught in the scar, was liberated in a flap which was turned inside the mouth. The edges of the flap from the neck were drawn beneath the skin margins of the facial wound and united with mattress sutures of horsehair. *Result:* At the extremity of the flap a portion of the margin about five-eighths of an inch in length sloughed, and the flap along the whole upper border of the wound separated.

On March 5, 1904, the edges of the opening into the mouth where the flap had separated, were freshened and sutured. The scar behind the angle of mouth between upper and lower jaws was again cut.

Result: The median portion of the line of apposition united, leaving a small opening posteriorly and a larger one about two-fifths of an inch in length at the antero-superior angle, at which latter situation the skin surface of the flap was everted for about two-fifths of an inch.

On April 4 the pedicle was divided, and an attempt was made to close the two small openings. Previous to this operation the child could separate the front teeth three-sixteenths of an inch and could chew. While under the anesthetic the jaws were spread so that there was one-half an inch between the front teeth.

Recurrence of noma: On the third day following this operation there was ulceration around the stitches and a high rise of temperature. On the fifth day the wound at the posterior opening continued to increase in size, was malodorous, and resembled a recurrence of noma. The culture report stated the case to be one of true diphtheria. Antitoxin was given. However, the diagnosis was found to have been faulty. The noma in the meantime had continued to eat away the flap until about half of that portion which had filled the facial defect was completely destroyed. A slough covered the outer surface of what remained of the flap within the latter area. On April 13, 1904, wide excision of the disease was effected. Some carious bone was removed. The raw surfaces were treater with pure carbolic and alcohol. There was a prompt drop in temperature, followed by recovery.

Bacteriological Findings.—Through an incision made through healthy tissues down upon the outer limit of the disease, scrapings were taken from the zone peripheral to the necrotic area, from which Dr. Flournoy obtained a bacillus in pure culture, which he described as follows: "The culture contained bacilli, pure, resembling the moderately long forms of true diphtheria bacilli. These are about five times as long as they are wide, occur singly, are in general slightly curved, and contain granules which stain metachromatically. They also show a slight irregularity in their diameter. The growth on agar is somewhat more extensive than that of the *Bacillus diphtheriæ*, being quite abundant after twenty-four hours, and showing a smooth, pearly white surface. On transplantation to blood serum (Loeffler's) they show a fairly abundant, rather thick growth, and the same morphological characteristics." It is an interesting fact that at a subsequent time Dr. Flournoy found a pure culture of this same bacillus in another case of noma, from which scrapings had also been taken from the tissue beyond the area of necrosis.

On March 19, 1906, the opening through the face into the mouth was found to have completely closed. The lower jaw was held in almost complete ankylosis. The child took food through an opening caused by the loss of a tooth. The skin over the lower jaw opposite the defect, corresponding to the area occupied by the remnant of the skin flap brought from the neck two years previously, was loose. *The operation now planned* was to split this area of loose integument off the lower jaw, through an incision made below the body of the latter, without cutting through into the mouth; then to line this pocket with a skin flap taken from the arm, and afterwards to cut through the top of the pocket into the mouth, divide freely the scar tissue attached to the lower jaw, and depend on the epithelial growth from the transplanted skin and the mucous membrane to cover the raw surfaces.

A second plastic operation was done on March 19, 1906, as above outlined. The Italian method was practised, having constructed a jacket and helmet of soft leather, as employed by Berger ("Chirurgie de Francisco Durante," 1908, I., p. 273). To accustom the patient to the fixation apparatus, she had worn the same at night for two weeks preceding the operation. The arm-flap was planned with a view to avoiding cicatrization that might impair the movements of the shoulder and elbow joints. The posterior leg of the flap ran from a point half an inch below the acromial angle downward and backward for about six inches over the postero-external aspect of the arm. The anterior leg began at a point about half an inch external to the anterior axillary fold, ran downward and backward parallel to the posterior leg to a point about an inch above the level of the termination of the latter, so that the extremity of the flap was cut diagonally. The width of the flap was about two inches. A greater length of the flap could have been gained by extending the anterior incision upward toward a point over the clavicle half an inch internal to the coracoid process, but at the operation this was found to be unnecessary. Three-quarters of an inch of the extremity of the flap was folded on the pedicle, and this tent-like fold was drawn by sutures into the pocket in the cheek. The head was fixed with the chin pointing toward the right shoulder. To maintain this position the right wrist was first strapped to the left shoulder close to the neck, and the space between the right forearm and left side of the face filled in with a wedge-shaped pad, the latter also passing beneath the chin. These measures prevented rotation of the head to the left, as well as too great depression of the chin toward the chest. A posterior point on the left side of the helmet was also drawn by a strap toward the left shoulder which rotated the chin toward the right shoulder, as well as tended to tilt it upward in the air. The molding movements of the head were limited by a sling beneath the right elbow, its extremities buckled one to either side of the fore part of the helmet. To clear the right side of the face, the sling was raised off the right temple by a roll of gauze laid just below the buckle. The folded extremity of the flap, lining the skin side of the pocket, sloughed. The portion of the flap against the lower jaw grew into place.

On May 21 the pedicle was divided an inch and a half from its site of attachment to the lower jaw,

and the free extremity of this distal piece was turned upward into the pocket to line its outer wall. A cicatrix involving the anterior axillary fold was removed and the pedicle was sutured into the gap, to prevent a recurrence of contraction at this situation.

On June 29 the piece of transplanted skin was divided into two parts, and the top of this now skin-lined pocket was cut through into the mouth. The scar behind the angle of the mouth was divided freely downward at its attachment to the lower jaw. A thick scar posteriorly over the molar teeth, when cut, allowed a spread of about three-quarters of an inch between the front teeth. The teeth on the right side of the lower jaw were found to be sunken into the alveoli.

After Treatment.—On July 4 Dr. F. O. Kendall fitted an interdental splint which maintained a spread of the front teeth of about half an inch, but by the middle of August its introduction became difficult owing to cicatricial contraction, and it had to be left out. The granulating surfaces were kept apart with gauze, and the growth of epithelium over them stimulated with a chinosol ointment, six grains to the ounce.

Subsequent Operations.—Recurring scar contractions behind the angle of the mouth and at the angle between the jaws were cut again on September 20, 1906, and finally on January 31, 1907. Before the latter operation the eye-teeth could just about be separated. At this last operation these two scars were cut very widely into the surrounding tissues, after which the treatment was as follows: To keep the wounds open while the epithelium was skinning over, they were spread daily with forceps. Rubber tissue, as less destructive to epithelial growth, was laid in the wounds in place of gauze, and chinosol ointment was used to stimulate epithelial growth. This treatment was more effectual in antagonizing the scar contraction than any previously employed. At the end of six weeks the epithelium had almost entirely covered the ulcers which had contracted somewhat, but not so much as on previous occasions. On March 17 the spread between the left upper eye-tooth and lower bicuspid which were opposite each other, was three-eighths of an inch. On May 14 this spread between the same teeth was one-quarter of an inch. The patient was encouraged to chew gum.

January, 1910. After nearly three years there is some mobility between the teeth on the right side. The patient can chew solid food on the left side. The incisor teeth can be little more than just separated. Food is introduced through a spread between the teeth.

Observations: (1) Since bacteria in pure culture could be demonstrated at the periphery of this disease which invades the tissues by a peripheral advance, and since in this case excision of the noma peripheral to the area of induration and treatment of the cut surface with pure carbolic acid and alcohol, completely arrested the progress of the disease, it would seem as though the bacteria at the periphery of a noma might be regarded as the causative factor in its production, and that treatment of the disease by excision of it beyond the line of bacterial advance would be a rational one.

(2) The case demonstrated the feasibility of the Italian method of skin-flap transplantation, with the use of Berger's flexible soft leather apparatus of fixation.

47 East Thirty-fourth Street.

THE QUICK METHOD OF EXAMINING STOOLS, AND ITS SIGNIFICANCE FOR DIAGNOSIS AND TREATMENT OF SOME INTESTINAL DISORDERS.

By M. GROSS, M.D.,

NEW YORK.

The general practitioner should be familiar with the examination of stools and should acquire a rapid and reliable method for the purpose. By examining the feces it is possible not only to gain a rapid survey of the work which the intestines perform or omit to perform, but also to draw some conclusions as to the nature and localization of the disorder. There is, of course, the difficulty to deal with that two or even three different ferments act in the same way for certain nutritive substances, and that one ferment may have a vicarious action for and take the place of another.

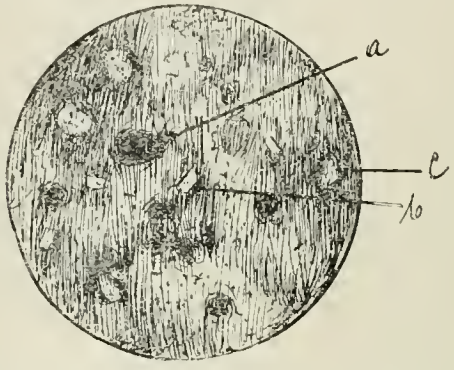

Fig. 1.—Normal test-diet stool; *a*, soap; *b*, muscle fiber; *c*, potato cell.

Method.—In the first place examine the stool after a mixed diet, then, after administration of castor oil, so as to eliminate from the intestine any residue of food, prescribe a test diet for three or four days. In certain chronic or neglected diarrheas it is even advisable to prescribe a bland diet for two or three days, because an organ in the "delirium" of its function cannot very well be accepted for diagnostic purposes. After an ordinary meal the stool is examined for the purpose of comparing it with the work performed by the intestine after the test meal. But conclusions from the findings after an ordinary meal can in no way be made to determine the true intestinal function because here there may be a concatenation of factors, such as quantity, quality, and mixture of ingesta, which would unduly falsify the picture. Artificially produced peristalsis should likewise be excluded. Apparently fatty stools here only indicate the presence of excessive quantities of fats with high melting points. Meat stools with connective tissue are met with, when the gastric intestine has been fed with meat in too fresh or half raw a condition, or with too large quantities of meat. Of course, it is just the repetition of these insults which are instrumental in causing the pathological state. Similar conditions prevail with carbohydrate stools: The organs are finally unable to respond to the unusual demands made upon them. Again, the uniformity of the foods containing an excess of albumin, fat, or carbohydrates seems to exert an influence upon the digestive powers. Thus, for instance, carbohydrates are better borne with the addition of fats, while the persistent uniformity of diet becomes harmful in the end.

All that has so far been said furnishes, therefore, sufficient cause for the necessity of a test diet. That of Strassburger-Schmidt keeps tolerably close with-

in the limits of the average diet: Intestines which can digest this diet without any appreciable residues will well be able to contend even with passing irregularities.

This test-diet (Strassburger-Schmidt) consists of the following: Morning, coffee, tea or cocoa with

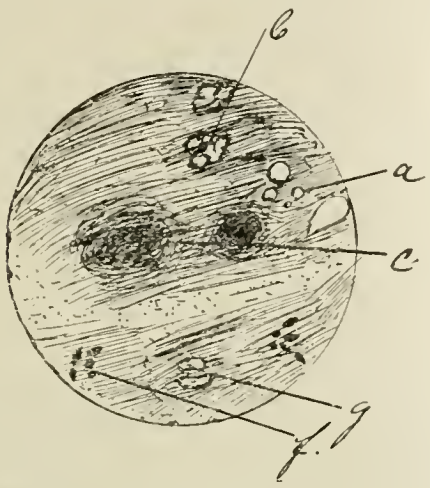

Fig. 2.—Normal test-diet stools; *a*, neutral fat drops; *b*, free fat; *c*, soap; *f*, bacilli; *g*, undigested starch.

much milk, oatmeal with milk, a soft-boiled egg, a roll with much butter. Noon, bouillon, if desired, quarter lb. of lean minced beef roasted in butter, half raw inside, a whole plate of finely ground potatoes, tea with milk, a roll with butter, and evening, oatmeal with plenty of milk, one or two eggs cooked in any desired way, or roast veal, if preferred, or roast lamb, a roll with butter and tea with milk.

Now, a thin, evenly spread layer of fresh feces is placed upon a black ground for macroscopic examination. A small piece the size of a pin-head of feces is spread with a glass rod in a thin transparent layer upon a slide for microscopic examination, taking care that the layer is slightly thicker at the edges. Only a thin layer gives a good, clear view and, besides, allows a rapid admixture of the chemicals which are to be added and frequently renders the rubbing on the slide unnecessary. The slightly thicker parts raise the coverglass a little, thereby admitting of an easier admixture of the fluids added for biochemical examination.

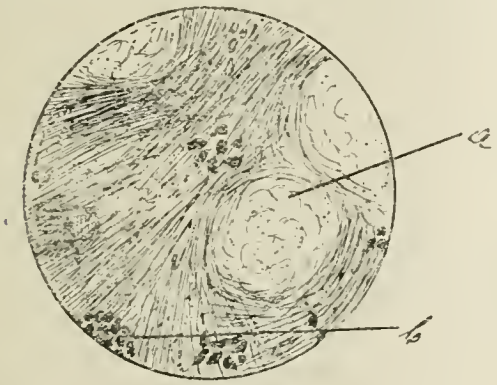

Fig. 3.—Normal test-diet stools; *a*, potato cells; *b*, bacilli.

In cases of obstipation glycerin suppositories are employed to obtain the feces rapidly, or in certain cases a glass rod is inserted into the rectum, as for instance when examing for Schaudinn's amebæ. Amebæ die rapidly, and it is therefore necessary to spread the mass upon a warm slide. A dose of Carlsbad salts sometimes accelerates their appearance. Where there is a suspicion of parasites, it is sometimes advisable to contrifugate the watered feces before examination.

Normal Test-Diet Stool.—Macroscopic. Light brown, after cocoa somewhat darker, odor not of-

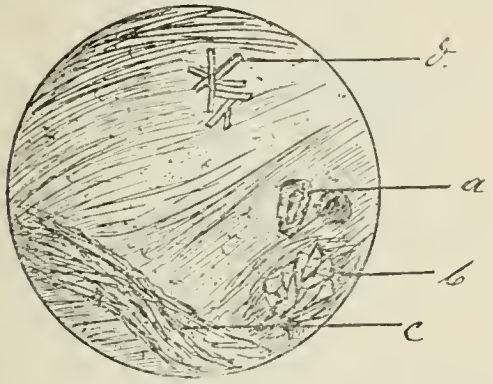

Fig. 4.—Test-diet stools; *a*, soaps; *b*, yellow granules (Nohnagel); *c*, connective tissue; *d*, calcium sulphate crystals.

fensive, of formed or semi-soft consistency, reaction neutral or slightly alkaline. This is examined by simply placing wet litmus paper upon the stools and noting the reaction upon the offside of the paper.

Microscopic.—In the basal substance formed by the detritus a number of round, dark spots of different sizes are at once visible under a Leitz lens No. 3, which prove to be deposits of soaps by biochemical examination. Figs. 1, *a*, and 2, *c*). Besides there may be a few isolated colorless, yellowish, or yellowish brown remnants of muscle fibres (Fig. 1, *b*) ; also a few lighter, roundish spots which prove to be potato cells under a Leitz lens No. 7 (Figs. 1, *c*, and 3, *a*), but frequently these are absent. There may also be found isolated drops of neutral fat with a dull shine (Fig. 2, *a*) and free soap deposits (Fig. 2, *b*), which are sometimes of cracknel shape ("Kringel," Schmidt), (Fig. 4 *a*). There are a few colorless granules of undigested starch or faintly stained by a diluted Lugol solution (Fig. 2, *g*) and sparse blue bacilli (Fig. 2, *f*). There are also yellow stained yeast cells (Fig. 8), crystals, and residues of cellulose.

Pathological Stool after Test-Diet.—Fat stools. Macroscopic. Light, foamy, tough, of rancid odor, and acid reaction. Microscopic. Plenty of neutral fat in colorless or yellowish drops with a dull lustre,

Fig. 5.—Fatty-acid crystals.

also in irregular roundish shape. Fatty acids. In the shape of long, pointed, lustrous needles of fatty acids (Fig. 5), or less often as irregular, shiny, small deposits and lancet-shaped plaquelets. Soaps. Aside from the above-mentioned soap deposits there are "free" colorless or yellowish deposits and short soap

needles, often in bundles and sheafs (Fig. 6), also in "Kringel" shape or fragments of same (Schmidt). Irregularities in the assimilation of fats are found in biliary stasis (icterus), in disturbed pancreatic secretion (in which case there are also many muscle fibers, in the stool) and in disturbed secretions of

Fig. 6.—Soap crystals.

the small intestine, but then there is neither icterus present, nor biliary colored matter (hydrobilirubin), nor muscle fibers.

When there is complete occlusion of the pancreas, the stool contains much neutral fat, abundance of muscle fibers, and biliary colored substances (as opposed to hepatic fat stools) and often shows putrefaction (as against hepatic stools in which there is no putrefaction).

Meat Stools.—Macroscopically are dark, of putrid odor, with visible muscular remnants which are often embedded in connective tissue. Microscopically, the entire field appears strewn with conglomerates of muscle fibers and many fibers entirely undigested. (Fig. 7). Further are seen the so-called "yellow granules" of Nothnagel (Fig. 4, *b*), which impart even on macroscopic examination an appearance as if the stools were sprinkled with brown poppy seeds and prove to be layers of closely arranged light-yellow deposits often embedded in mucus, which according to Schmidt are also muscular remnants. An abnormal quantity of muscle fibers in the stool is present with deficient secretion of the pancreas and small intestine and with peptic gastric insufficiency (Cohnheim). "Whatever muscle fragments have once passed through the ileocecal valve, will be excreted with the feces" (Nothnagel).

Connective Tissue Stools.—Macroscopic. Spread upon a dark plate, the stool shows connective tissue

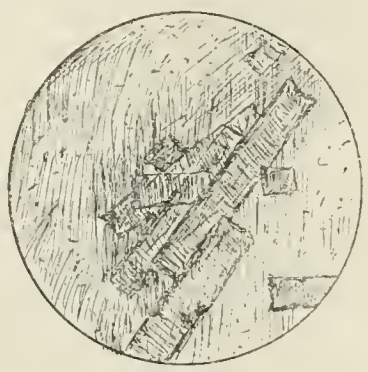

Fig. 7.—Muscle fiber.

in the shape of white particles, which, microscopically, appear as white fibers with distinct demarkations, as against mucus (Fig. 4, *c*). Connective tissue is rather frequently found in normal, but mixed stools, and the quantity differs according to diet and method of cooking of the meat partaken of, especially with people who eat raw meat and eat rapidly. The presence of connective tissue in the stool after a test-meal points to gastric disturbance (Schmidt) in the sense of insufficiency or absence of HCl.

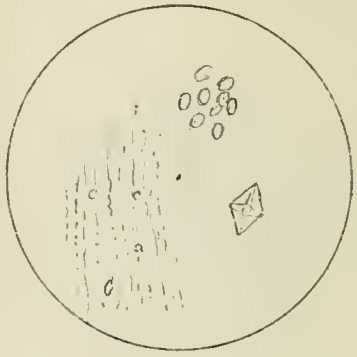

Fig. 8.—Mucus and yeast cells.

Mucous Stools—Catarrhal Stools.—Macroscopically there are either large pieces of mucus lying on the stool or mucus is intimately mixed with the stool. In the latter case these appear as small, glassy, transparent spots, if the mass has been spread with water upon a glass plate and held against the light. Microscopically is seen a structureless, transparent, basal substance. The mucus does not show any demarkation such as exists in connective tissue. (Fig. 8). Sometimes it is only the presence of epithelia, pus corpuscles or bacteria, embedded in the basal substance, which imparts to it a distinct appearance. The so-called cell deposits of Nothnagel (*"verschollte Epithelien"*) are also frequently found embedded in the mucus (Figs. 10 and 12). They look like dull shining, irregular deposits and have a soapy reaction; they are really nothing but dried-up cells impregnated with fatty soaps (Schmidt). The presence of mucus in the stool points to an inflammatory process in the intestine. Macroscopic mucus is always referable to the large intestine, as is also the mucus of colitis membranacea. The finer the mucus is distributed and mixed with feces, the higher the part of the intestine in which it originated. The fact that mucous stools which have persisted for a number of years often disappear after a short proper treatment, perhaps never to reappear, is an indication of the presence of a kind of protective arrangement of the intestinal mucosa against extraneous irritation; as the irritating cause

Fig. 9.—Mucus, treated with acetic acid.

is removed, the abnormal secretion ceases, while the inflammation itself may disappear gradually.

Carbohydrate Stools.—Macroscopically these are light brown or golden yellow, permeated with air bubbles, of a sour and pungent odor smelling of bu-

tyric acid, of acid reaction, often of fluid consistency with macroscopically visible potato remnants. A drop of Lugol's solution placed on the slide shows in some cases graduated stains of pink, violet, and dark-blue spikes and points. Microscopically the starch is mostly encountered in filled cells (Fig. 3), less often free as remnants not enclosed by cell membranes, and least frequently in the shape of starch granules and free starch which is still faintly iodine colored. The raw, uncolored starch granules are recognized by their intense lustre (Fig. 2, *g*). Besides, carbohydrate stools present a number of granular bacteria (*Bac. butyricus,* Strassburger) and still more numerous others of various sizes and shapes, such as rods of cocci or bacteria arranged in rows and heaps, which stain more or less blue with diluted solution of iodine. Frequently the bacteria are present in such numbers that they pervade the entire specimen (Fig. 3). Carbohydrate stools point to a disturbance of the small intestine, because neither stomach nor large intestine has any considerable part in the digestion of starch, and point to a disturbed secretion (fermentation dyspepsia of Strassburger-Schmidt) which, when long continued, may lead to real inflammation of the intestine with decomposition of the inflammatory transudate (Schmidt) in fact to a "putrefactive stool" which is frequently fluid and of putrid odor, alkaline re-

Fig. 10.—Mucus with epithelia.

action, with many remnants of fat, meat, and coffin-lid crystals.

Also in the case of hyperacid gastric juice there is, according to Tabora, irritation of the intestinal mucosa with disturbed pancreatic digestion, increased peristalsis, in short manifestations as are present in fermentation dyspepsia. The presence of large quantities of bacteria staining with iodine also points to deficient carbohydrate digestion of sugar especially. With reduced ingestion of carbohydrates they may disappear entirely. Principally acid stools seem to furnish them with favorable growing conditions.

All the findings of undigested food remnants in the stool, so far enumerated, do not often occur singly, but rather in numerous combinations. In the present communication these few disturbances have been emphasized because of their frequent occurrence and their practical importance, as it is often possible to effect a rapid and definite cure, even in long-standing cases, by the timely institution of therapeutic measures.

Microchemistry.—The introduction of chemical agents and coloring material into the microscopic specimens forms an important part of the fecal examinations, principally because our observations furnish a means to elucidate the nature of the specimens from the changes which may be said to occur under our very eyes.

Method.—Either the reagent is mixed with the preparation on the slide itself, or the drop is simply introduced upon the slide at the same time as the specimen is examined under the microscope. The latter method, however, is only successful if the mass is spread in a very thin layer. Acetic acid

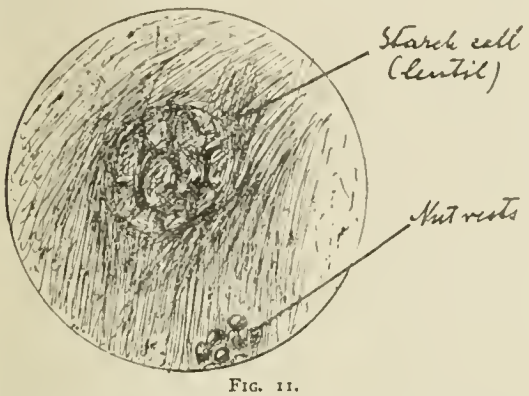

Fig. 11.

(30 per cent.) makes muscle fibers swell up. A solution of liquor kali caustici (15 per cent.) dissolves them. Millon's reagent stains them red. A strong solution of iodine (iodine 1.0; calium iodate 2.0; water 50.0) stains starch granules blue. A solution of potassium swells them up. For staining the bacteria it is necessary to use diluted solutions of Lugol's solution.

An alcoholic Sudan III solution stains neutral fats red. Heat melts the fatty acids into drops which turn into solid deposits as they cool off. Heating with an addition of acetic acid produces fatty acid crystals. Liquor kali caustici or alcohol dissolves them; otherwise they behave like neutral fats. Acids and heat make the soaps disappear, assuming the shape of drops. Sulphuric acid and heat make the soaps disappear and assume the shape of drops and calcium sulphate crystals (Fig. 4, *d*). Mere heat does not melt them. Acetic acid makes the structure of connective tissue disappear—with the exception of the elastic fibers which, on the contrary, assume a more distinct appearance—as against mucus which shows up more distinctly under acetic acid: precipitation.

Therapy.—In all disturbances of the intestinal function, with the exception of atonic constipation, the ingesta should, generally speaking, be prepared so as to be digestible without leaving any residue, which means that such food is to be discarded as

Fig. 12.—Soap and epithelia.

produces a great residuum or is digested with difficulty (vegetables, fruit, black bread, raw meat, smoked meat), or chemically irritate the intestine (spices, also pure milk in some cases). Patients' mastication should not be depended upon. Nor has the ingestion of recrementitious food proved an in-

variable success in the case of obstipation; on the contrary, the expected stimulating effect has frequently been absent (on account of the abnormal over-assimilation of food, vegetables even, etc.), in these patients, undesirable irritative manifestations having occurred instead. In these cases there should rather be rest of the digestive organs and reduced irritation. Frequently, by prescribing restful diet, long-standing obstipations may be removed (constipatio spastica).

In cases of gastrogenic diarrhea it is necessary to abstain for a time from all meat, in the place of which meat juice, milk in suitable form, soft-boiled eggs, and similar easily digested foods should be taken. In cases of putrefaction only gruels, milk, soups, and buttermilk, should be subscribed; later on meats may again be tried in small quantities, beef well boiled or fried, or fish.

Where there is disturbed fat digestion, fats with a low melting point which easily emulsify, should be ordered, as milk, cream, butter, and few eggs. In order to render the milk more easily digestible, Schmidt adds 0.2 salicylic acid to the quart, slowly increasing the quantity of the milk. The same object is often attained by diluting the milk half with water, or, better still, by mixing it with well-boiled cereals. This also applies to intestinal fermentation and putrefaction. By the use of properly prepared cereals, mixed with milk, the time is also shortened for which the food remains in the stomach.

In carbohydrate disturbances it is not necessary to forbid altogether carbohydrate products, but there should be careful preparation of the starch (cooking in a double boiler and straining). A rapid effect is often attained in intestinal fermentation by instituting a diabetes treatment or a pure fat meat diet with gradual additions of carbohydrates, omitting, however, potatoes. The order of starch digestibility is as follows: Wheatmeal, finest maize meal, rice meal, finely ground arrow root, grits, crackers, toast, sago, rice, white bread, potatoes.

Medication is frequently unnecessary. Hydrochloride acid and pepsin in gastrogenic diarrheas with achylia; pancreon in pancreogenic diarrheas; irrigations of the stomach in fermentation stool (gastric atony) and diastase have proved successful.

315 Second Avenue.

THE EARLY DIAGNOSIS OF CARCINOMA OF THE SIGMOID.*

REPORT OF A CASE.

By G. A. FRIEDMAN, M.D.,

NEW YORK.

CHIEF OF THE DEPARTMENT FOR INTERNAL MEDICINE AT THE MOUNT SINAI DISPENSARY, CHIEF OF THE DEPARTMENT FOR DISEASES OF STOMACH AND INTESTINES TO THE BETH-ISRAEL DISPENSARY; VISITING PHYSICIAN TO THE YORKVILLE HOSPITAL.

Gastric carcinoma may run such a latent course that no tumor is palpable during the entire illness. This is all the more true of carcinomata of the different portions of the intestine, and if one insist upon palpating a tumor before committing himself, an early diagnosis of carcinoma of the large intestine is often out of the question.

It was thought that the form of the stools and the presence therein of abnormal elements (*e. g.* blood and pus) might be of service in reaching a diagnosis, particularly in the case of carcinoma of the sigmoid flexure. Stools of the form characteristic of stenosis, however, are not always observed, and the presence in them of blood and pus indicates merely that there is an ulcerative process in the lower part of the large intestine, which is, of course, not necessarily carcinoma.

The following are the most important points in the diagnosis: (1) The gradual development and gradual increase of constipation in an individual formerly quite normal in this respect. (2) If this constipation require the exhibition of powerful cathartics until, finally, even high irrigations do not completely empty the bowel, a stenosis of the lower part of the large intestine is present. (3) If the patient be forty or more years of age, carcinoma is probably the cause of the stenosis.

The following case shows the importance of early diagnosis: The patient, B. H., age 63, was first seen in September, 1908, in consultation with Dr. Blitzer.

Past History.—Except for an attack of cough and "asthma" two years ago which lasted for one year and was relieved after going to the mountains, the patient has always been well. Bowels have always been very regular and there was never any previous abdominal disturbance. Has had two attacks of gonorrheal urethritis and two "chancres." An abscess developed in the left groin after one of these, thirty or more years ago. No history of secondary symptoms. Wife has had ten children and one miscarriage. Two childen died; the others are well.

Present Illness.—Began gradually ten to twelve weeks ago with cramp-like hypogastric pain. Eight or nine weeks ago noticed a rather sudden development of constipation. At first the ordinary cathartics overcame this more or less, but gradually grew less and less effectual until about ten days ago constipation became absolute; since then bowels move with enemata only. The abdomen has become enlarged and the patient has vomited nearly everything taken for the last four or five days. Has taken no solid food for eight days because of burning pain and vomiting that follow immediately. Has lost ten pounds in weight in about two months and feels very weak. At times pains are more marked in left side of abdomen.

Physical Examination.—General condition, poor; poorly nourished; emaciated though not cachectic; marked dilatation of venules of nose; temporal arteries prominent. Eyes, pupils unequal; right larger; outline irregular and fixed; left pupil small; reacts slightly to light and accommodation. Conjunctivæ congested, right more so than left. Media of right eye cloudy. Skin, dry and loose; shows an urticarial eruption about the abdomen. Lymph nodes, no special enlargement. Mouth, no teeth. Gums atrophic. Tongue moist and heavily coated. Pharynx and uvula relaxed; no adhesions. Chest, barrel shaped with marked flaring of free borders of ribs. Marked retraction above both clavicles. Lungs, signs of emphysema with marked dullness over both apices. Heart, borders obscured by emphysema. Sounds clear; no murmurs. Action regular and of fair force. Pulse, equal, regular and full. Artery wall moderately thickened. Abdomen shows increased prominence of hypogastrium, extending upward on both sides to about the level of the umbilicus; surface is rather uneven; one marked prominence corresponding to the sigmoid reaching from the anterior superior spine to the crest of the ilium. On palpation the swelling seems to be due to distended intestine. The abdominal wall is tense but not rigid. Sigmoid is palpable as seen, and over it gurgling is felt and peristalsis is at times visible. There

*Read before the Eastern Medical Association, November 12, 1909.

is marked tympany over the distended area. Moderate general tenderness, most marked in the umbilical region. No tumors felt; no fluid. Liver, dullness from sixth intercostal space to costal margin; liver not felt. Spleen not felt. Genitals, oval scar on left side of corpus cavernosum; scar in left groin; testes negative. Rectal examination not made. Extremities, knee jerks diminished; no edema. Urine, usually amber, clear, acid, 1018-1030, no albumin, few ephithelial and pus cells.

September 19, a preliminary operation for carcinoma of sigmoid was performed by Dr. Berg. The abdomen was opened by an incision passing through the fibers of lower part of left rectus muscle. The sigmoid was found distended but free and was delivered through the wound. A very marked annular constriction was found obstructing the bowel at the site of a tumor. The mesentery (meso-sigmoid) was exposed and a few very small lymph nodes were found and removed for examination. A large loop of sigmoid having been drawn out, the meso-sigmoid of this part was tied off. Peritoneum closed. Drainage. Dry dressing. Eight hours after operation the gut above and below the constricting tumor was opened and large rubber drainage tubes inserted. Profuse fecal discharge.

September 21, Tumor resected, tissues gangrenous. Pathological report, 13856. Adenocarcinoma. Dr. Mandlebaum. October 29, crushing of spur of artificial anus. Enterotribe applied for two and one-half hours. Redundant portion of lower loop removed. November 10, after repeated application of the enterotribe only about three-fourths inch of spur remains. November 11, operation; closure of artificial anus. Under local anesthesia the margins of the skin and the deeper layers were loosened up and the gut freed for a short distance. The granulations were trimmed away and a rough closure of the ends of the gut made with chromic sutures. Over this the layers of wound were closed. Drainage tube to the gut and wet dressing. November 14, profuse fecal discharge from wound which has broken down. Temperature, 103°. December 11, closure of artificial anus. After local anesthesia the mucosa was separated from the skin and the same technique employed as on November 11. January 5, discharge relieved; artificial anus persists. Temperature: On September 20, temperature rose to 104°. From September 21 to 22 it ran between 99° and 101.6°. On November 13 and 14 it was between 99° and 103°. From December 1 to 3, 99.2° to 104°; December 16, 103.2°; otherwise practically normal. In July, 1909, perfect closure of artificial anus. Patient gained in weight, 20 pounds.

123 East Ninety-Fifth Street.

EXAMINATION OF URINE AT THE BEDSIDE.

By GEO. RICHTER, M.D.,

ST. LOUIS.

Enterprising manufacturers have supplied us with a large number of contrivances for examination of urine at the bedside. There are test-papers, pellets, elegant little pocket-cases, and what not. The only drawback is, that, as occasion arises, we happen not to have the "multum in parvo" on hand, or it is somehow out or order. What we want to know when seeing a case for the first time is this: Is there albumin or sugar present? If so, then we must investigate further as to quantity, etc., and, meanwhile, we are sufficiently posted to act in an emergency, such as coma or convulsions.

The tests which I suggest are readily improvised in any household. No apparatus and no chemicals are required. As to their reliability, there is no question. They are among the most delicate; they are generally known; still, I believe, rarely remembered.

To test for albumin, take an ordinary spoon. Half fill with the urine, add a small pinch of salt, and heat over a lamp or a match. When it begins to steam and bubble, add a few drops of vinegar. This test will indicate the presence of albumin unmistakably, is more delicate than the Heller test, and possesses the advantage that the color of the urine is not changed while a white precipitate or turbidity appears.

To test for glucose is even simpler. Dilute one or two drops of urine with a few drops of water in a spoon. Carefully evaporate to dryness with little heat. Now slowly heat further, when, almost suddenly, a characteristic orange-brown spot and an unmistakable odor of caramel will prove the presence of sugar without the shadow of a doubt. One-fifth of a milligram (1/3 of 1 per cent.) is thus easily detected. Urine free from sugar colors a smoky black, and, on heating further, emits its peculiar urinous odor. When there is 1 per cent. or more sugar present, a very characteristic lump of sugar-coal is formed. *Probatum est!*

407 North Broadway.

LETTERS TO A NEUROLOGIST.

By JOSEPH COLLINS, M.D.,

NEW YORK,

PHYSICIAN TO THE NEW YORK NEUROLOGICAL INSTITUTE.

IV.

My Dear Doctor:—Last summer I wrote to you about myself and you very kindly told me that I might send you a synopsis or outline of my case. I did not do so then because for some weeks after I received your letter I was free from the mental harassment which has been my curse for twenty years. Now it is upon me again and I want to know what course to pursue.

As I wrote you, my case is one of dual personality, or perhaps I should say, of two personalities. I presume nearly everyone is somewhat of a "Dr. Jekyll and Mr. Hyde," but I have never heard of any case like mine in real life. Then the fact that each one of my personalities is dominant for a certain length of time and that they have about equal strength, seems to me most unusual. For twenty years I have been conscious of this but I have never before spoken to anyone about it for fear of being misunderstood. I am not insane, but my mind is not as normal as it might have been had I received help many years ago. When A has the whip hand in my nature I am convinced X is crazy. I call my personalities A and X.

A is truthful, earnest, honest, generous, just and deeply religious. X is impish, impulsive, whimsical, humorous, destitute of moral responsibility, bent on harassing A, and willing to go any length to accomplish this purpose. The ceaseless warring of these two personalities has often brought me to such a state of desolation and despair that death has seemed the only happy solution.

I must have been about seventeen or eighteen when I began to realize that I possessed two distinct personalities. One of the first occurrences that impressed this on me was when I went to a store to buy a book. When I got there, I stole it. I had the

money in my pocket to pay for it, but X made me steal it in order to taunt A with her depravity. The next day I returned the book and told the proprietor what I had done and that I wished to make restitution. He returned the book to me and asked me to keep it. Apparently this action had a good effect upon me, for I do not recall having deliberately stolen anything of value since.

At this period I was in the high school and during the entire time stood first or second in the class. During my last year a principal came whom X liked to tease and humiliate, so she promptly lowered her standing to the bottom of the class, although A, if she had not been submerged, could easily have kept her place in the class. After graduation A wished to enter college, but being without funds and no scholarship being available at the time, it seemed impossible. However, she interested a friend, who presented her case to President ————————, and he appointed a meeting with A. When the day came, X would not let A go. A now took up painting, going to a studio, where her work excited much interest and where she made commendable progress. In the middle of the term, X left. This angered the artist very much and X was very much gratified. A again took heart and began the study of music and voice culture with an excellent teacher. X soon started a flirtation with him and his pupils began to leave him. A then returned to her books and studied at home alone for a year, and subsequently passed the teacher's examination for both State and City. She secured a position as substitute teacher for two years, and then as a regular teacher for five years. During four years of this time, A and X were each living separate lives. A's interests were in the cottage home with the aged father and crippled mother; in the primary class of which she was teacher, and in the church and Sunday-school. X one day entered a matrimonial agency and contracted with the proprietor to find a husband for her. She did not intend to marry, she did it for pure mischief. The delight of her life was in tormenting A by writing hundreds of letters to men, describing the quiet, honest face of A in language that would have made Venus tremble with envy. X also took a special delight in describing A's accomplishments, the record of her church works, her "form divine" and other attractions to ensnare the male sex. These were not true, for A is thin and tall and her looks are not of a nature to justify particular mention. (You recognize the fact that I claim A as the ego; yet I do not think I am really either A or X.)

X allowed two gentlemen from this agency to call upon her, three others she met upon the street by appointment, and she paid constant visits to the agency. The people who ran it became tired of X and asked her to keep to her contract, namely, marry or pay them a certain sum. X refused to do either. They threatened exposure, and when it came X delighted in it, but A nearly died.

X triumphed over A in another way shortly after this. On a Friday afternoon, without a hint to anyone, she closed the door of her schoolroom and never entered it again. She walked into the Commissioner's office and announced that she had resigned. Then followed eighteen months with X in the supremacy. She lived an out-of-door life, was happy because the sun shone, did not enter a church, went wherever she liked and at the end of that time demanded her former position as teacher. The members of the Board were astonished and perplexed. She had left of her own volition and had never made any complaint. X adopted an air of injured innocence, which deceived the public into believing her a martyr and the Board her persecutors. One gentleman of the Board, believing that X really desired to return, and displaying an unusual interest in her, told her to leave it with him, he would "manage it somehow," although there was no vacancy, only she "must not tell on him." X promptly told and got him into trouble.

I do not wish to weary you, my dear Doctor. I could tell you of incident after incident in all these weary years, some of them trifling and commonplace, others striking at the root of my existence, my daily bread.

A few years ago A got on top and squeezed X down for three years. She did this by taking up church work as a lay sister and going amongst the poor and uneducated, endeavoring to teach them how to live hygienically and morally. Wearing the garb and cross, every hour that she devoted to the crowded East Side was Heaven on earth for A, but the long years of mental conflict had so wearied the physical body that it was unable to bear the strain of this hard work, and A, with much heartache and many tears, gave it up. I do not think she would have been obliged to give it up if X had not nagged her constantly.

Then X had her way for a year and a half. During that time I got in very good physical condition and were it not that I did many things which met with my absolute disapproval, I should have thought that I was fairly well. Soon after this I accepted the position of missionary of a Sunday-school and kept it for two years, until I was offered the place which I now hold as assistant to the Pastor of ———————— Church, of this city. It is because of circumstances which have arisen here that I am writing you. Something must be done and I do not know what course to take. I am accustomed to being misunderstood, but repetition does not seem to render it any easier to bear. I am used to taking the blame for results for which I can give no cause. How can I say to the public, "Do not blame me; I am A, not X. I suffer only as a supersensitive woman can suffer at the misdoings of X, but I am powerless to prevent it." Suppose I should offer such an explanation, would I not be thought insane?

When the Pastor of this church came to it a few years ago he found a dilapidated building, a small congregation and no enthusiasm. By hard work he has tripled the membership, he has built a beautiful church and he has developed a true Christain spirit amongst his flock. When he asked me to work with him and offered me a small salary, I was delighted to do so, and for two or three months I did my work in a satisfactory manner. I worked with enthusiasm and felt that at last I had found a true mission. The spiritual contentment which came to me at that time is one of my pleasantest memories.

It so happened that I knew of the parentage and early life of this clergyman. X knew that there were certain features of it which would humiliate and chagrin him if they were communicated to his parishioners and X promptly communicated it. This made a great scandal, which pleased her impish self hurt the church and the clergyman, and, more than all, caused poor A indescribable suffering. X used her influence against the church and the clergyman in several instances. Many of the members sided with her and it was decided to give her a holiday. When I returned, X was still dominant. During

my absence, malicious reports were circulated about me, and on my return I received a cool welcome. I see many persons looking suspiciously at me and I am sure that when two or more of them gather together I am frequently the topic of conversation. The members all treat me as Christ would not have treated Mary Magdalen, out of whom he cast *seven* devils. People do not understand why I stay. I want to stay, hoping that they may understand, perhaps even help me.

What shall I do? No one but God knows what I am suffering. It seems as if I could not bear it any longer. Is there no comfort, no help for such unfortunates as I? Somewhere I have read that dual personality is a form of disease. I am sure that it is. If you do not treat sufferers like myself, can you tell me if hypnotism would be of any help to me, or can you suggest *anything* that would bring relief from the increasing ascendancy of X?

"Every man hath a good angel and a bad angel attending on him in particular all his life long."
BURTON. *"Anatomy of Melancholy."*

Dear Madam:—Your letter has interested me and I feel the most sincere sympathy for you. To answer it fully, I should have to write a treatise on life in its relation to mind and conduct. Whether I am able successfully to treat your case or to relieve your sufferings will depend entirely upon yourself. As you very truthfully say, had the opportunity to orient you come years ago, the task would have proved less difficult for both of us. Plastic youth, not rigid maturity, is the time to effect change.

One thing I must say to you in the beginning. You come to me for help and you tell of your troubles with much apparent frankness, but in reality you have withheld much, and you have consciously, or half-consciously, tried to place yourself in the best possible light, even though by so doing you have created a wrong impression. In the diagnosis of a case, a physician often reaches his conclusion more from the patient's manner, expression, attitude—more from what is unsaid or only partly said—than from the patient's words. This is especially true of the neurologist, for the troubles of the mind are often expressed by physical and unmistakable signs, and "he who runs may read." Moreover, in cases such as yours, interpretation of what the patient says is oftentimes a large part of the physician's problem. Emotional and psychopathic individuals are rarely able to give an accurate and dispassionate account of their ills.

Look back over the years of trouble you have had with X and think whether at times the gentle A has not become a little weary of well-doing and perhaps held out the welcoming hand of fellowship to X, only to regret in bitterness of spirit the consequences of her folly. Has not X at times become ashamed of speaking evil, lying and slandering, and thus paved the way for A to rise triumphantly? You have a dual personality, but that is not a disease, nor yet a crime; we all have a dual personality dating from the days when there were "two people in a garden" and the serpent whispered honeyed words in the ear of our first mother. Eve had her X as well as you; Cain was dominated by his X when he killed Abel; Saul forsook X and turned to A on the road to Damascus and his name was changed to Paul. In after life he taught that the material side of nature ought to be treated with contempt and that the spiritual side could be made to absorb it entirely. But, as someone has well said, Paul could never have become the vehement and vigorous spiritual apostle had he not profited by the passion and vigor of Saul, the persecutor. But the greatest encouragement for you is that Paul, after years of sacrifice, was still crying, "Oh, wretched man," finds peace at length and victory. I may remind you, although it may seem beyond the province of the physician to do so, that such saintly souls as Paul won their victory finally by the aid of the Matchless One, who was able to sympathize because he himself was tempted.

The psychological basis for the conflict that goes on within you is undoubtedly the presence of antagonistic instincts which are your birthright. Everyone possesses these antagonisms. They do not always conflict with our consciences. Take, for example, the instinct of sociability, which leads the individual to seek society, perhaps to be unhappy in solitude, and on the other hand, shyness, which leads him to avoid meeting people. This is one of the commonest conflicts. These "ancestral voices prophesying war" are common in even the lower animals. The deer is trapped, for instance, by appealing to his uncontrollably curiosity, which leads him to overcome his pronounced shyness. It is evident that this conflict goes on in every individual, for it is the basis and superstructure of our entire moral education. If we didn't have it, there would be little necessity for a moral code. In milder cases of dual personality without separation of memories, we are merely dealing with character tendencies more or less organized and systematic which pull in opposite directions. In your own case there is a little more definite organization of these tendencies, but if you are really sane as you say you are, you should not have much difficulty in orienting yourself.

Dual personality has been a favorite topic with the poet and the novelist. Possibly you have never seen this verse from the pen of one of our minor poets and sanest philosophers. Does it not describe your predicament?

"Within my earthly temple there's a crowd.
There's one of us that's humble, one that's proud;
There's one that's broken-hearted at his sins
And one that unrepentant sits and grins.
There's one that loves his neighbor as himself
And one that cares for naught but fame and pelf.
From much corroding care would I be free
If once I could determine which is me."

Do you not think that my friend, a man of saintly nature, childlike simplicity, and unalloyed morality, who wrote the following lines had a dual, a triple, or a quadruple personality?

"What, I say, know you
Of my deep, inward, real, wonderful life?
My wild emprizes, foolishnesses, fears,
Failures, and shames, and all but acted crimes;
My half-mad waking dreams, O, yes, stark mad;
My spiritual comedies, my glooms—
Unutterable, intense, and without hope;
My secret, true and unpraised heroisms;
My tragedies—played on the bare soul's stage,
With no eye witnessing but mine, alone—
Great God! not thine, I pray, not thine, not thine!
GILDER.

In reality, the explanation of your predicament is not a difficult one, though the moral struggle reaches at various times the intensity of a combat. Both A and X are *you;* that is to say, you have in your ego power for good and for evil. You must do

that which all your predecessors who have won out have done, namely, nurture the former and starve the latter. You cannot lay unction to your soul for the good deeds of A and lay the blame for all your misdoings on the broad shoulders of X as though X were a thing outside of you. Your heaven and hell dwells within your own breast and you must put it clearly and honestly in your mind that X is you and that you are responsible for X. You are ready to admit that A is you; why not X as well? You cannot resent being misunderstood by others when you do not understand yourself. We cannot progress without a knowledge of ourselves. Knowledge of self is often supposed to be merely a knowledge of our defects and shortcomings, whereas, in reality, it extends infinitely further and embraces our whole nature. To know oneself in repose is not enough nor is it enough to know oneself in the past or in the present. There are those who, by their knowledge of the past and keen insight into the present, have the power of knowing themselves in the future. These have faith in themselves, have control over themselves and verily are "captains of their own souls" because of their wisdom of thought and action. This is the reason why anything which leads to knowledge of ourselves is of value, and by knowledge of ourselves, I do not mean what we would be, nor what we would have others think us, but what we really are.

"Wad some power the giftie gie us, to see ourselves as ithers see us" is not of so much importance as to know ourselves for what we are worth; to be able to realize calmly and dispassionately all that we are capable of being and doing. To set up a true ideal, not a graven image with feet of clay; to have a broad, clear vision not only helps us, but makes the world a better place for others. Knowledge is power and knowledge of self is the greatest power of all, for to know the weak spot in one's armor is to guard against attack, while to know one's strength is to gain independence of thought and action. From this knowledge one is led simply and naturally to a knowledge of others and thus may be developed an intuitive sympathy with human nature.

There is said to be an aura, or atmosphere, surrounding each one of us, and the electrical negative or positive force emanating from this makes us magnetic or antagonistic to our fellowmen. Perhaps it is more a question of an understanding mind than an atmosphere, and a sympathetic soul than an electrical current. There are latent forces in the human soul, which, when known and understood, can be developed and used to control the worst in us and exalt the best. First we creep, then we crawl, then we stand alone, and finally we walk. This is typical of mental and moral, as well as physical development.

Specifically, what is the ego that you recognize has imperious possession of you for a considerable portion of the time? What are its distinguishing traits and characteristics? Lying, affectation, and folly, are they not? You have heard it said, I have no doubt, that the inclination to lie is a basic one; that is, it is natural to the species man in his early years, just as all creative effort is natural—and pleasing. Happily, it can usually be eradicated, but in some instances with difficulty, especially in those persons who have imagination. Liars idealize themselves, depicting occurrences and relating circumstances in order to make for the liar's advantage. As soon as he understands that his conduct in this respect is a solvent of social union of every kind—family, community, friendship—he realizes that it comes into violent conflict with the fundamental motive of conduct, namely, self-interest, and if it is not too fixed a habit, he gives it up.

Obviously, it has become a habit of your depraved ego, and so also has affectation, or the desire to be considered what you are not. This is certainly the only possible explanation of your conduct at the matrimonial agency. You wished to be thought not only a modern Juno, but a Daphne and Proserpine as well, when in reality you were only the daughter of an American working man, and had you comported yourself as such, it is not unlikely that you would long ere this have shared the joy of nature in generation.

If you have been forced to struggle with your native instincts and passions, you have not told me. You have not even hinted at this side of your nature, although I ought certainly to have some knowledge of this conflict if I am to advise you how to deal with it, how to utilize it in moral and social growth. Everyone in the world who amounts to anything, it matters not the sphere of life in which his energies have developed, has had materialistic propensities which at times have influenced him, at other times have overwhelmed him, but which he has finally subdued because of the appeal made to him by ideals of conduct.

In reality, what is it that you are seeking? Is it to have a spiritual life entirely and absolutely cut off from the material? If so, sometime when A is in the ascendency, you should take monastic vows and become a member of a community whose life is devoted to the spiritual and ascetic, but if you believe that you would not have been endowed with certain instincts unless there was a biological need for them and unless they had a definite significance, then you had better conform your conduct so that it will meet with the sanction of the community in which you live, realizing at the same time that you have rudimentary impulses which are as natural as the simple reflex impulses of sneezing and coughing.

You ask me finally if there is any help for you in hypnotism. Were I to answer that question categorically, I should say yes. But hypnotism is no mysterious occult power or force; it is merely suggestion acting in a soil which in one way or another has been rendered more fertile. A careful study of the life of St. Augustine ought to do more for you than hypnotism, or, if you prefer one of your own sex, of St. Theresa. They had dual personalities with a vengeance, and X had the whiphand a considerable portion of their lives. In reality, you have the same power to mold your life to your own will as they had, if you but see the necessity of it; that is, if you have the requisite motive. Self-control and patience will be your best medicines, and as surely as you have the sincere wish to conquer, so surely will the victory be yours. To live down the effect of the actions of X will be an effort, but take heart and do not be discouraged,

> "Our acts or angels are, for good or ill,
> Our fatal shadows that walk by us still."

Do not sit with folded hands, moaning or sulking over the difficulties to be overcome, or lamenting lost opportunities. Fight the battle valorously and you will find, month by month, that X will become more feeble as A becomes more dominant and insistent.

Let me hear of you soon again and let me hear of victories won.

Yours sincerely,

MEDICAL RECORD.

THE INCREASED COST OF LIVING AND THE PUBLIC HEALTH.

BESIDES the personal problems of domestic economics which the increasing cost of living presents to all as individuals, there is a less apparent but none the less important feature of this question which presses for recognition and consideration by us in our capacity as the medical guardians of the public health and welfare. Whatever may be the cause of the present excessive and steady rise in prices, of its actual results there can be no doubt, nor can there be any question as to the profound significance of these results in relation to health matters with which, as physicians, we are directly concerned. In any thorough inquiry into the causes and prevention of disease, and especially in the study of its epidemiology, the earnest investigator soon finds himself necessarily passing beyond the confines of medical practice and following remote causes into the domain of sociology and industrial and political economics, with all that these imply. Predisposing conditions dependent on habits of life and environment play a most important part in the development of disease, and as such quite properly come within the purview of the medical man. Beside recognizing the existence of such conditions, he is also interested in ascertaining whether they and their consequences may or may not be avoidable. If the former, it becomes his duty as a humanitarian to insist that the proper remedy and corrective shall be applied.

The more one inquires into the causes of disease and suffering in mankind, the more the conclusion seems inevitable that, within certain limits, prevention is largely a matter of the expenditure of money. This applies to the group as well as the unit. The recent sanitary survey of Pittsburg, for example, showed that the heavy toll of sickness, sorrow, and death exacted by typhoid fever in that community could have been prevented at no excessive financial outlay; and applied to the individual it is a matter of common knowledge that such as can afford healthful surroundings and a generous standard of living will largely escape tuberculosis and other infectious diseases. It is, of course, quite a legitimate function of writers of textbooks on medicine and hygiene, solemnly to prescribe good food, proper shelter, suitable clothing, sufficient exercise and recreation, and abundant sunlight and fresh air as general essentials in the preservation of health. But of what practical use are such excellent recommendations to that large and growing class of poor persons whose best endeavors can probably never suffice to procure these sanitary essentials? All such things cost money, and often the items which are popularly supposed to be free to everyone, such as sunlight and fresh air, are really the most expensive of all. In New York, for instance, they are one of the most costly luxuries of the rich, as anyone who proposes to secure a sunny, well-aired residence in this densely populated community will very quickly learn. It is true that the public streets and parks afford fresh air and sunshine, but the very class which needs their benefits most is largely prevented by industrial and economic conditions from enjoying them. How is the man whose condition in life is such that the loss of a day's labor is almost a catastrophe, to make proper use of these public life-preserving privileges? He must work to live, even though such work actually shortens life itself.

The fact cannot be disregarded that there is a very large class in this country which habitually stakes the labor of today against a bare subsistence and shelter for tomorrow. While even among those better off the present increased cost of living is a matter of serious importance; among the first-named class such increase means nothing less than domestic tragedy which cannot long delay of due reflection in the statistics of disease and death. Those in comfortable circumstances may have to curtail the luxuries, but will still be able to procure the actual necessities of life, and some may even profit by the general and tremendous rise in prices. Members of trades unions, by threats and strikes, may or may not be able to bring about an increase in their wages commensurate with the cost of living, and more or less synchronous with rise in the prices of the necessities of life. But there is a still larger social element in the community, consisting of unskilled laborers, clerks, and others outside of the artisan class, whose lack of organization and cooperation prevents them from securing prompt adjustment and increase of income to changing and increased conditions of outgo. Few such have a margin of surplus sufficient to permit of their undertaking some new and more gainful occupation, and economic readjustment on a better basis is for them only gradually possible. The law of supply and demand takes a long time to work out in the favor of such, and they are forever and unavailingly pursuing the retreating ideal of a modest existence which shall be provided with the ordinary and reasonable decencies and comforts of life.

It is a matter of statistics that about sixty per cent. of the wage of the laboring class is expended for food. With the cost of food increased, as it has been, by an average of about one-half within the last five years, the unfortunate whose wages have not been proportionately raised in the same period now finds himself in a very serious situation, for it is not possible without such increase to maintain former habits of diet. It is quite true that with a scientific knowledge of dietary standards and the proximate composition of food stuffs, one can

devise bills of fare from the cheaper food materials which, if not quite so palatable, will still entirely satisfy the nutritive needs of the body; but it is equally true that the poorer class, for whom this would be specially desirable, can possess no such scientific knowledge. The laboring man secures his balanced dietary largely through instinct, the pleasure of taste, and the desire for variety. He does not know that in a dietary meats can best be supplanted by legumes and partly so by certain cereals, that vegetable oils are cheaper and just as nourishing as animal fats, or that oatmeal more generally meets the needs of the body than does rice. Finding that animal foods, which have chiefly yielded his protein and fats, are passing beyond his reach, he naturally turns to the cheaper and more bulky vegetable foods, which under his selection may usually be regarded as relatively innutritious and containing an excess of carbohydrates with deficiency of the other food elements. Such an insufficient or improperly balanced dietary results in more or less chronic malnutrition, which directly favors the occurrence of disease through the diminution in the defensive powers of the organism which it causes. Just as there probably never was a famine not accompanied or shortly followed by pestilence, so in a less spectacular way chronic malnutrition in the impoverished of a community results in their greater susceptibility to disease, the scattered cases of which are individually inconspicuous but loom significantly large when aggregated in vital statistics.

But under-nourishment and its direct results are not the only evils which the high price of food stuffs brings in its train. It means retrenchment all along the line. With the price of the prime necessity—food—steadily advancing, and with no wage surplus to fall back upon, in order to get enough of the general type of nourishment to which he is accustomed the worker will very probably have to move into a cheaper, less sanitary habitation, accepting through necessity the greater risks to health and life which attend overcrowding, dirt, and insufficient air and light. He must economize in the matter of artificial warmth, and cannot afford to buy either as many or as comfortable garments—especially since the price of the latter has greatly increased while their warmth and wearing quality have materially diminished. Recreation and physical idleness which relieve nervous strain and render the struggle for existence less wearing must be foregone.

With every step down and back in the scale of right living, forced by the excessive costs of ordinary necessities, the resistance to disease and the expectation of life must steadily diminish in the poorer classes. As physicians, it becomes our plain duty to inquire why such retrogression in comfort and health should be possible under our civilization. We tend too much, as a profession, to be easily satisfied with surface conditions. Our campaign for sanatoria for tuberculosis, for example, only reaches an ill which has been allowed to develop, and our education of the public in its prevention calls for habits, conditions, and modes of life which very few would not be glad to adopt, but which even fewer are ever financially able to secure. Too few of us stop to consider that health costs money, that increasing difficulty of maintaining a reasonable standard of living inevitably predisposes to sickness, and that we cannot do our full duty as humanitarians until, as citizens and men of affairs, we probe deeper and help to determine and remove the ultimate economic and industrial causes of disease and death from the body politic.

THE ROLE OF THE PHYSICIAN IN THE CAMPAIGN AGAINST TUBERCULOSIS.

The awakening of the general public to a vivid sense of the menace of tuberculosis and the consequent efforts which have been put forth to check its spread has been one of the most remarkable features of a public health character during the past twenty years. In some ways, the ordinary individual has become too greatly alive to the dangers of tuberculosis, and in several instances has gone to extreme measures in his endeavors to avoid contagion. Objections are being made in various parts of this continent to the presence in large numbers of personal suffering from pulmonary tuberculosis, and occasionally fear of the disease has carried communities to absurd and almost inhuman lengths. The consumptive has rights, and it must be borne in mind that a consumptive in a city is a greater menace than a colony of such persons segregated in the open country. However, the question before us is as to the bearing of the modern tread of medicine upon the medical man. It is obvious to all that the man in the street is taking a more or less intelligent interest in matters of health than was formerly the case. For this state of affairs, of course, the physician himself is chiefly responsible. He has made, to a great extent, medicine and surgery common property. He has drawn away the veil of mystery which used to surround matters medical, and the layman has been invited to judge for himself up to a certain point.

In the *Journal of the Michigan State Medical Society* for December, 1909, A. S. Warthin of Ann Arbor discusses the effect upon the changed order of things, or rather the coming changed order of things. He sees clearly that the rôle of the physician is becoming yearly more that of a preventor than of a treater of disease, and hails the time as an era of hope for the physician rather than one of despair. With regard to the aspect of affairs in connection with tuberculosis, Warthin deals with the relation of the rank and file of the profession to the crusade against tuberculosis, and asks the question as to whether physicians are taking their proper places as leaders of antituberculosis education in their own communities. So far as Michigan is concerned, he declares that physicians are not taking the places which belong to them by virtue of their calling. A year or so ago, the Michigan State committee appointed by the general committee of the International Congress on Tuberculosis, held in Washington in 1908, met in Ann Arbor to discuss plans for the inauguration of a State antituberculosis campaign. At this meeting one physician was chosen in every town in the State having a population of 1,500 or over, who should act as a local

organizer. One hundred and twenty physicians were chosen, and after repeated letters, pamphlets, reports, etc., had been sent to these local chairmen, only one-third of those chosen ever replied, and in some instances these responses were by no means enthusiastic.

Probably, if the whole country were canvassed in the same way as Michigan has been canvassed, the result would be similar. Medical men, as a rule, do not care to go outside the general routine of their work and excuse themselves on the grounds of being too busy, or that it will bring them into too great prominence and look like self advertisement. As Warthin points out, if the physician does not bestir himself the layman or laywoman, as the case may be, will take the matter out of his hand, and Christian Science bodies and Immanuel movements and the like will be founded to the detriment of society and the physician. The physician is the legitimate educator in questions relating to public health, and when the community at large demands education on such points, as it demands at the present time, the physician should adapt himself to the changed conditions, shake off his lethargy, and exhibit himself as a teacher and a pioneer in all that concerns the physical well being of the people.

Decapsulation of the Kidneys in Eclampsia.

During the past decade there has been an exceptionally large amount of research work done on the subject of puerperal eclampsia. Obstetricians, pathologists, and chemists have devoted their time and energies to the search for the cause of this obscure disease of pregnant womanhood with the result that, though the problem is yet far from solved, a number of more or less associated facts have been ascertained throwing considerable light upon the subject and pointing to the toxic origin of the disease. So far, however, as teaching us how actually to treat the eclamptic woman, these years have been sadly barren of fruit. It is a natural result when medical treatment fails to advance in any particular direction, that some should turn to surgery for aid. To a small degree this has occurred in the case of eclampsia, and in the *Deutsche medizinische Wochenschrift* for December 23, 1909, Johnsen has published a brief report of the performance of Edebohls' decapsulation of the kidney operation in three cases of this condition. Discouraged by his experience during the last two years, by a maternal mortality from antepartum eclampsia of 39 per cent., and in postpartum attacks of 55 per cent., he turned to surgery for help. His three cases were briefly as follows: The first was admitted in eclamptic coma. Before the spontaneous birth occurred there were eighteen convulsions, and, during the next three hours, five more. Then both kidneys were decapsulated without anesthesia, the deep coma rendering it unnecessary. The convulsions and suppression of urine lasted three days and disappeared, returned again on the fourteenth day, and finally cleared up on the twentieth. In all there were 148 convulsions, in spite of which the patient recovered, and was discharged well on the fortieth day. The second patient, also admitted in coma with marked edema, was delivered manually of a dead fetus. After this the sensorium remained clear and there were no convulsions. The patient, however, sank steadily, and on the third day was again unconscious and pulseless. Decapsulation was then performed. The mind cleared, the pulse returned, and the urine increased. The improvement was however but transient, and the patient died sixteen hours after the operation. The third woman was operated upon five hours after the birth of a dead child. A few convulsions occurred during the next few hours, after which the coma disappeared, and the excretion of the kidneys increased. On the fifth day, however, the temperature rose and the patient died of septicemia. Including these three cases, according to Johnsen, forty-two cases of kidney decapsulation have been reported in eclampsia, with eighteen deaths, a mortality of 43 per cent. As various other authors report their mortalities from eclampsia treated medically, as varying from 3.3 to 33 per cent., as it not infrequently happens that cases apparently hopeless do recover, and as recent research has pointed toward the condition being a manifestation of a general intoxication in which the kidneys play but a secondary part, it is scarcely likely that this operation will receive very general acceptance.

Hemorrhagic Varicella.

The occurrence of bleeding into the skin and from the mucous membranes during the progress of the acute eruptive fevers is far from a rare complication, and hemorrhagic varieties of measles, smallpox, and typhoid fever are common incidents in practice. In the case of varicella, however, though not unknown, it is extremely infrequent, and a fatal case of hemorrhagic chickenpox is a distinct curiosity. In the *Cleveland Medical Journal* for January, 1910, Elliott reports such a case. The patient was a boy four years of age. On the fourth day of what was apparently a very mild attack of chickenpox, he complained of pain in his stomach and vomited a small amount of blood. Upon examination at this time, beside the scabs of the healing eruption, were found pinhead-sized petechiæ, especially numerous over the face, thorax, and abdomen, and ecchymoses varying from 1 to 5 cm. in diameter on the scalp, forehead, abdomen, back, and thighs. In the mouth, under the tongue and on the tonsils, were seen circular slightly raised purple areas of hemorrhage. The internal organs appeared normal on examination, but there was a general enlargement of the lymph glands. The urine passed that night contained a large amount of albumin and much blood, but was free from casts. On the next day there were several fresh spots in the mouth, and those on the tonsils had become confluent and were oozing. The stools showed clots, but no fresh blood. The temperature varied from 99° to 100°. On that day, the child having inhaled a piece of chewing gum which could not be dislodged, tracheotomy was performed. From this he recovered uneventfully, and it was noted that the blood at the wound clotted in a normal manner. On the following day the urine was clearer but still contained some blood; the temperature was 100°, and the pulse 120. Hemorrhagic spots appeared on the eyes, one on the conjunctiva of the lid, and one just below the iris. The ecchymoses on the scalp were fading and those on the tongue and cheeks were practically healed. On the next day, the ninth of the varicella and the fifth since the appearance of the petechiæ, the child appeared to be recovering. His temperature was 100.5°, and pulse 130; the urine appeared normal; no blood was seen
